Abstract

The usual way to compare testing strategies, whether theoretically or empirically, is to compare the number of faults they detect. To ascertain definitely that a testing strategy is better than another, this is a rather coarse criterion: shouldn’t the nature of faults matter as well as their number? The empirical study reported here confirms this conjecture. An analysis of faults detected in Eiffel libraries through three different techniques—random tests, manual tests, and user incident reports—shows that each is good at uncovering significantly different kinds of faults. None of the techniques subsumes any of the others, but each brings distinct contributions.

1 Introduction

A substantial amount of research in software testing has been devoted to developing new or improving existing fault detection strategies. It is often hard to know how related tools and strategies compare in terms of their fault detection ability. Many studies [19, 20, 17, 28, 22, 40, 15, 23, 38, 25, 7] have tried to answer this question. Some studies have provided analytical answers such as subsumption; others have focused on the number of faults detected by the different strategies. In sum, there is almost no conclusive evidence that one testing strategy would clearly outperform another one in terms of the number of detected faults.

Earlier work [11, 12, 38] has led us to conjecture that the number of faults is too coarse a criterion for assessing testing strategies. In the experiments described in this paper, we investigate if the nature of faults is a more suitable discriminator between different fault detection strategies. This work’s main result is empirical evidence that different strategies do indeed uncover different kinds of faults.

The three fault detection strategies analyzed in this paper are manual unit testing, field use (with corresponding bug reports), and automated random testing. They are representative of today’s state of the art: the first two are widely used in industry, and the last reflects the research community’s current interest in automated testing solutions. By “manual unit testing” we denote any testing activity whose purpose is to find faults in a class or group of related classes, and in which a tester must write the code to create input objects and must also provide the oracle of the tests.

Although random testing is only one trend in current research, it is attractive because of its simplicity and because it makes test case generation comparatively cheap. Moreover, there is no conclusive evidence that random testing is any worse at finding faults than other automated strategies.

Random input generation delivers the best results when combined with an automated oracle, due to the numerous and untargeted tests that it produces. For a human it would be tedious to wade through these tests, of which only a small proportion reveal faults. The power of random testing can be fully exploited only if the pass/fail decision is automated. A great part of the work on fully automated testing [8, 14, 35, 36, 34] thus uses built-in test oracles in the form of contracts. These can either be written by developers — who indeed write contracts when possible [9] — or inferred by a tool [16] from runs of the system under test. Preconditions, postconditions and class invariants provide an automated oracle with a level of abstraction [39] that is usually far more fine-grained than the simple robustness assessment that can be obtained from checking whether or not the system crashed. Satisfying preconditions is a theoretical challenge [3], but not necessarily a practical one.

In the experiment presented here, we used the AutoTest tool [30] for investigating the performance of random testing. AutoTest performs fully automated testing of contracted O-O software: it calls the routines (methods) of the classes under test with randomly generated inputs (objects), and, if the preconditions of these routines are satisfied, it checks if contracts are fulfilled while running the tests. Any contract violation that occurs or any other thrown exception signals a fault. AutoTest’s strategy for creating inputs is not purely random: it is random combined with limit testing, as explained in §2. Previous experiments [11] have shown that this strategy is more effective at uncovering faults than purely random testing at no extra cost in terms of execution.
time, so we consider it more relevant to investigate the more effective strategy. As this strategy is still random-based but also uses special predefined values (which have a high impact on the results), in the rest of this paper we will refer to it as random+ testing. We ran AutoTest on 39 classes from a widely-used Eiffel library, called EiffelBase, which we did not modify in any way. AutoTest found a total of 165 faults in these classes. To investigate the performance of manual testing, we analyzed the faults found by students who were explicitly asked to test three classes, two created by us and one slightly adapted from EiffelBase. Faults in the field are taken from user-submitted bug reports on the EiffelBase library. We evaluated these three ways of detecting faults by comparing the number and distribution of faults they detect via a classification that contains 21 categories.

Contributions. Fault classifications have been used to analyze the difference between inspections and software testing. Yet, as far as we know, ours is the first study that (1) develops a classification of faults specifically adapted to contracted O-O software, and (2) uses this classification to compare an automated random testing strategy to manual testing, and to furthermore compare testing results to faults detected in the field.

The main results of the comparison are the following. Random+ testing is particularly good at detecting problems in specifications. It is not so good at detecting problems of overly strong preconditions, infinite loops, and “semantic” problems as discussed below. It detects most of the faults uncovered by manual testing, plus some. This suggests that random+ testing should be applied before human testers enter the loop. In addition, random+ testing finds only a small percentage of user-reported faults; this suggests that random+ testing cannot replace collecting bug reports from software users. A more general conclusion is that testing strategies should indeed be compared in terms of the kind of faults and not only of the number of faults that they find.

Although, as is the case for any empirical study, the applicability of the results is limited to the examined testing techniques and to the specifics of the tested code, other case studies can build upon our results by extending its scope to different testing methods and different types of tested systems, due to the composable nature of such studies.

Overview. §2 provides the background for random tests of O-O software. §3 presents a classification of faults. The experiments and their discussion are the subject of §4. After putting our work in context in §5, we conclude in §6.

2 Background

This section provides an overview of how AutoTest generates and executes random tests for Eiffel programs. The tool itself is not the focus of this paper and has been described previously [11, 12].

The units under test are routines of Eiffel classes. Assume that a class C defines a routine m with return type R and formal arguments p_1, ..., p_n of types C_1, ..., C_n. To test m, we must generate an object c of type C and actual arguments a_1, ..., a_n of types C_1, ..., C_n. In the absence of contracts, we would also have to generate an object r of type R representing the expected output. We can then execute c.m(a_1, ..., a_n), compare the resulting object to r, and check if the effect of m on c and the a_i is as expected. The inputs (the target object c and the argument objects a_i) can be generated through constructor calls, which themselves are routines and may need arguments; this requires a recursive generation procedure.

For contract-enabled languages such as Eiffel, JML or Spec#, there is an obvious simplification. Rather than explicitly describing the expected output through an object r, we can use the routine and class contracts. Upon execution of c.m(a_1, ..., a_n), we check if the postcondition of m and the invariant of C are satisfied. This gives us an oracle for free, in the form of postconditions and invariants. Because it is an abstraction, this oracle is usually not able to predict the precise values that are a result of executing the test. Of course, the contract itself may be incorrect (§3), but this is a general problem with oracles. Note that tests are only meaningful for calls (including to constructors) that satisfy their preconditions.

To obtain input objects for a routine, it is desirable not to create a new object each time with a constructor call, but also to keep a pool of available objects. This is because constructor calls tend to generate rather simple objects, not necessarily representative of the complex data structures that can arise during a realistic execution. AutoTest retains objects that have been created and stores them in the pool. Whenever it needs an object as target or argument for a call to a routine under test, it randomly picks one from the pool. After the routine call, it returns the object to the pool. With a preset frequency, AutoTest also generates a new object, which it adds to the pool. In this way, the objects in the pool are likely to get modified by the routines under test. When it needs values of primitive types, AutoTest either selects them from a predefined set of values which includes limit values, or randomly selects one of the possible values for that type, hence the name “random+ testing”.

Test case generation then means generating Eiffel code that creates objects and executing their operations – the routines under test. By running this code in an interpreter, contract violations and other unhandled exceptions are logged. These violations are the failures that AutoTest can detect.

We use the following terminology. A failure is an observable difference between expected and actual output; in this work they are the contract violations and exceptions logged by AutoTest. An error is a program state that is not in accordance with the intended state. Errors may (but
do not have to) lead to failures. A fault is the reason for the error and includes incorrect implementations and invalid specifications, i.e., specifications inconsistent with the actual requirements.

3 Classes of faults

Two dimensions characterize a fault in programming languages with support for embedding executable specifications: the fault’s location — whether it occurs in the specification or in the implementation; and the fault’s cause, the real underlying issue. The following paragraphs discuss both dimensions and introduce the resulting fault categories. The classification is not domain-specific. Although other fault classification schemes exist, as discussed in §5, we are not aware of any such schemes for contracted code.

Specification & implementation faults

In contract-equipped programs, the software specification is embedded in the software itself. Contract violations are one of the sources of failures. Hence, faults can be located both in the implementation and in the contracts. A specification fault is a mismatch between the intended functionality of a software element and its explicit specification (in the context of this study, the contract). Specification faults reflect specifications that are not valid, in the sense that they do not conform to user requirements. The correction of specification faults requires changing the specification (plus possibly also the implementation) [38]. As an example, consider a routine deposit of a class BANK_ACCOUNT with an integer argument representing the amount of money to be deposited to the account. The intention is for that argument to be positive, and the routine only works correctly in that case. If the precondition of deposit does not list this property, the routine has a specification fault. In contrast, an implementation fault occurs when a piece of software does not fulfill its explicit specification, here its contract. The correction of implementation faults never requires changing the specification. Suppose the class BANK_ACCOUNT also contains a routine add_value that should add a value, positive or negative, to the account. If the precondition does not specify any constraint on the argument but the code assumes that it is a positive value, then there is a fault in the implementation.

The notion of specification fault assumes that we have access to the “intended specification” of the software: the real specification that it should fulfill. When analyzing the faults in real-world software, this is not always possible. Discussing it with the original developers is also in most cases difficult or even impossible. To infer the intended specification, one must usually rely on subjective evidence such as the comments in the routines under test; the specifications and implementations of other routines in the same class; how the tested routines are called from various parts of the software system. This strategy resembles how a developer not familiar with the class would proceed to find out what the software is supposed to do.

Classification of faults by their cause

Some kinds of specification and implementation faults tend to recur over and over again in practice. Their study makes it possible to obtain a finer-grained classification by grouping these faults according to the corresponding human mistakes or omissions — their causes. By analyzing the cause for all faults encountered in our study, we obtained the categories described below. The classification was created with practical applicability in mind and mainly focuses on either a mistake in the programmer’s thinking or a misused programming mechanism.

Specification faults. An analysis of specification faults led to the following cause-based categories, grouped by the type of contract that they apply to.

1. We identified the following faults related to preconditions.
   - **Missing non-voidness precondition**: A precondition clause is missing, specifying that a routine argument, class attribute, or other reference denoted by argument or attribute should not be void (null) is missing.
   - **Missing min/max-related precondition**: A precondition clause is missing, specifying that an integer argument, class attribute, or other integer denoted by an argument or attribute should have a certain value related to the minimum/maximum possible value for integers.
   - **Missing other precondition part**: A precondition is under-specified in another way than the previous cases.
   - **Precondition disjunction due to inheritance**: with multiple inheritance it can be the case that a routine merges several others, inherited from different classes. In this case, the preconditions of the merged routines are composed, using disjunction, with the most current ones. Faults in this category appear because of this language mechanism (e.g., because the precondition of one parent class is true).
   - **Precondition too restrictive**: the precondition of a routine is stronger than it should be.

2. Faults related to the postcondition include **wrong postcondition** (the postcondition of a routine is incorrect) and **missing postcondition** (the postcondition of a routine was omitted).

3. Faults related to class invariants include only one: the **missing invariant clause** — a part of a class invariant is missing.
4. Faults related to check\textsuperscript{1} include only one kind: 
\textbf{Wrong check assertion} — the routine contains a check condition that does not necessarily hold.

5. Finally, the following faults apply to all contracts.

\textbf{Faulty specification supplier}: a routine used by the contract of the routine under test\textsuperscript{2} contains a fault, which makes the contract of the routine under test incorrect. (The fault can be located either in the contract or in the implementation of the supplier, but, since it affects the contract of the client, we classify it as specification fault.)

\textbf{Calling a routine outside its precondition from a contract}: a failure is triggered because the contract of the routine under test calls another routine without fulfilling the latter’s precondition.

\textbf{Min/max int related fault in specification} (other than missing precondition): the specification of the routine under test lacks some condition(s) related to the minimum/maximum possible value for integers. (Our examples so far do not cover floating-point computation.)

The categories in this classification have various degrees of granularity. The reason is that the classification was derived from faults obtained through widely different mechanisms: by AutoTest; by manual testers; by users of the software. The categories emerged by inductively identifying recurring patterns in existing faults, rather than by trying to fit faults deductively into a scheme defined a priori. Where such patterns could not be found, the categories are rather coarse-grained.

\textbf{Implementation faults}. The analysis of implementation faults led to the following cause-based categories.

\textbf{Faulty implementation supplier}: a routine called from the body of the routine under test contains a fault, which does not allow the routine under test to function properly.

\textbf{Wrong export status}: this category refers particularly to the case of creation procedures (constructors), which in Eiffel can also be exported as normal routines. The faults classified in this category are due to routines being exported as both creation procedures and normal routines, but which, when called as normal routines, do not fulfill their contract, as they were meant to be used only as creation procedures.

\textbf{External fault}: Eiffel allows the embedding of routines written in C. This category refers to faults located in such routines.

\textbf{Missing implementation}: the body of a routine is empty, often signaling an uncompleted attempt at top-down algorithm design.

\textsuperscript{1}An Eiffel check instruction is similar to an “assert” in C and C++. It states a condition that should be fulfilled at a certain point in the execution of a block of code. If contract monitoring is on and the condition does not hold, the execution triggers an exception.

\textsuperscript{2}In Eiffel, contracts can include function calls.
library developers to not be faults or those that referred to the .NET version of EiffelBase, which we cannot test with AutoTest. Our analysis hence refers to the remaining 28 bug reports fulfilling these criteria. The bug reports were submitted between the beginning of 2005 and the end of 2007, so they span a period of almost 3 years.

To determine how manual testing compares to random+ testing, we organized a competition for students of computer science at ETH Zurich. 13 students participated in the competition. They were given 3 classes to test (which we also tested with AutoTest to compare the results). The task was to find as many faults as possible in these 3 classes in 2 hours. Two of the classes were written by us (with implementation, contracts, and purposely introduced faults from various of the above categories), and one was an adapted version of the STRING class from EiffelBase. Table 1 shows some code metrics for these 3 classes: number of lines of code (LOC), number of lines of contract code (LOCC), and number of routines. We intentionally chose one class that was significantly larger and more complex than the others to see how the students would cope with it. Although such a class is harder to test, intuition suggests that it is more likely to contain faults. The students were not allowed to modify the classes under test in any way.

The students had varying experience in testing O-O software; most of them had had at least a few lectures on the topic. 9 out of the 13 students declared that they usually or always unit test their code as they write it. They were allowed to use any technique to find faults in the software under test, except for running AutoTest on it. Although they would have been allowed to use other tools (and this was announced before the competition), all the students performed only manual testing. The code they were given included contracts, which the students used as oracle: at the end of the competition, they had to deliver test cases revealing the faults that they had found, through a contract violation or another exception.

### 4.2 Random+ testing vs. user reports

Table 2 shows the distribution of specification and implementation faults (1) found by random+ testing (labeled “AutoTest” in the table) 39 classes from the EiffelBase library and (2) recorded in bug reports (provided by the maintainers of the library) from professional users. Note that the results in this table refer to more classes tested with AutoTest than for which there are user reports: even if there are no user reports on a specific class, the class may still have been used in the field.

![Table 2. Random+ Testing vs. User Reports](image)

Almost two thirds of the faults found by random+ testing were located in the specification of the software, that is, in the contracts. This indicates that random+ testing is especially good at finding faults in the contracts. In the case of faults collected from users’ bug reports, the situation is reversed: almost two thirds of user reports refer to faults in the implementation.

Table 3 presents a more detailed view of the specification and implementation faults found by AutoTest and recorded in users’ bug reports, grouping the faults by their cause, as explained in §3. This sheds more light on differences between faults reported by users and those found by automated testing, and exposes strengths and weaknesses of both approaches. One difference that stands out relates to faults related to extreme values (either Void references or numbers at the lower or higher end of their representation interval) in the specification. Around 30% of the faults uncovered by AutoTest are in one of these categories, whereas users do not report any such faults. Possible explanations are that such situations are not encountered in practice; that users do not consider them to be worth reporting; or that users rely on their intuition on the range of acceptable inputs for a routine, rather than the routine’s precondition, and their intuition corresponds to the intended specification, not to the erroneous one provided in the contracts.

A further difference results from AutoTest’s ability to detect faults from the categories “faulty specification supplier” and “faulty implementation supplier.” They mean that AutoTest can report that certain routines do not work properly because they depend on other faulty routines. In our records users never report such faults: they only indicate the routine that contains the fault, without mentioning other routines that also do not work correctly because of the fault in their supplier. An important piece of information gets lost this way: after fixing the fault, there is no incentive to check whether the clients of the routine now work properly, meaning to check that the correction in the supplier allows the client to work properly too.

Random+ testing is particularly bad at detecting some categories of faults: too strong preconditions, faults that are a result of wrong operator semantics, infinite loops, missing routine implementations. None of the 165 faults found by AutoTest and examined in this study belonged to any of the first three categories, but the users reported at least one fault in each. It is not surprising that AutoTest has trouble detecting such faults. First, if AutoTest tries to call a routine with a too strong precondition and does not fulfill this precondition, the testing engine will simply classify the test case as

invalid and try again to satisfy the routine’s precondition by using other inputs. Second, AutoTest also cannot detect infinite loops: if the execution of a test case times out, it will classify the test case as “bad response.” This means that it is not possible for the tool to decide if a fault was found or not — the user must inspect the test case and decide. Third, users of the EiffelBase library could report faults related to operators being implemented with the wrong semantics. Naturally, to decide this, it is necessary to know the intended specification of the operator. Finally, AutoTest cannot detect that the implementation of a routine body is missing, unless this triggers a contract violation. By code analysis, one can automatically find empty routine bodies, yet not decide if this is a fault. Note that in these cases, the overall number of detected faults is rather low, which suggests special care in generalizing the findings.

We also ran AutoTest exclusively on the classes for which users reported faults to see if it would find those faults (except three which AutoTest cannot currently process as they are either expanded or built-in). When run on each class in 10 sessions of 3 minutes, AutoTest found a total of 268 faults (However, 183 of these faults were found through failures caused by the classes RAW_FILE, PLAIN_TEXT_FILE and DIRECTORY through operating system signals and I/O exceptions, so it is debatable if these can indeed be considered faults in the software.) 4 of these were also reported by users, so 21 faults are solely reported by users and 264 solely by AutoTest. AutoTest detected only one of the 18 implementation faults (5%) reported by users and 3 out of the 7 specification faults (43%). While theoretically it could, AutoTest did not find the user-reported faults belonging to such categories as “wrong export status” or “case not treated.” Longer testing times might, however, have produced different results.

4.3 Random+ testing vs. manual testing

To investigate how AutoTest performs when compared to manual testers (the students participating in the competition), we ran AutoTest on the 3 classes that were tested manually. The tool tested each class in 30 sessions of 3 minutes, where each session used a different seed for the pseudo-random number generator. Table 4 shows a summary of the results. It displays a categorization of the fault according to the classification scheme used in this paper (the category ids are used here; they can be looked up in Table 3), the name of the class where a fault was found by either AutoTest or the manual testers, how many of the manual testers found the fault out of the total 13 and a percent representation of the same information, and finally, in the last column, x’s mark the faults that AutoTest detected.

The table shows that AutoTest found 9 out of the 14
faults that humans detected and 2 faults that humans did not find. The two faults that only AutoTest found do not exhibit any special characteristics, but they occur in class MY_STRING, which is considerably larger than the other 2 classes. We conjecture that, because of its size, students tested this class less thoroughly than the others. This highlights one of the clear strengths of the automatic testing tool: the sheer number of tests that it generates and runs per time unit and the resulting routine coverage.

Conversely, three of the faults that AutoTest does not detect were found by more than 60% of the testers. One of these faults is due to an infinite loop; AutoTest, as discussed above, classifies timeouts as test cases with a bad response and not as failures. The other two faults belong to the categories “missing non-voidness precondition” and “missing min/max-related precondition.” Although the strength of AutoTest lies partly in detecting exactly these kinds of faults, the tool fails to find them for these particular examples in the limited time it is given. This once again stresses the role that randomness plays in the approach, with both advantages and disadvantages.

### 4.4 Summary and consequences

Three main observations emerge from the preceding analysis. First, random+ testing is good at detecting problems in specifications. It is particularly good with problems related to limit values. Problems of this kind are not reported in the field but tend to be caught by manual testers.

Second, AutoTest is not good at detecting problems with too strong preconditions, infinite loops, missing implementations and operator semantics. This is due to the very nature of automated random testing.

Third, in a comparison between automated and manual testing (i.e., not taking into consideration bug reports), AutoTest detects almost all faults also detected by humans, plus a few others. For model-based testing, this confirms the findings of an earlier study [38] and speaks strongly in favor of running the tool on the code before having it tested by humans. The human testers may find faults that the tool misses, but a great part of their work will be done at no other cost than CPU power.

### 4.5 Discussion

AutoTest finds significantly more faults in contracts than in implementations. This might seem surprising, given that contracts are Boolean expressions and typically take up far fewer lines of code than the implementation (14% of the code on average in our study). Two questions naturally arise. One, are there more faults in contracts than in implementations, i.e., do the results obtained with AutoTest reflect the actual distribution of faults? Two, is it interesting at all to find faults in contracts, knowing that contract checking is usually disabled in production code?

We do not know the answer to the first question. We cannot deduce from our results that there are indeed more problems in specifications than in implementations. The only thing we can deduce is that random testing that takes special care of extreme values detects more faults in specifications than in implementations. Around 45% of the faults are uncovered in preconditions, showing that programmers often fail to specify correctly the range of inputs or conditions on the state of the input accepted by routines.

It is also important to point out that a significant proportion of specification errors are due to void-related issues, which are scheduled to go away as the new versions of Eiffel, starting with 6.2 (Spring 2008), implement the “attached type” mechanism [33]. This removes the problem by making non-voidness part of the type system and catches violations at compile time rather than run time.

We have not provided a comparison with a fully random strategy, but rather used random+ testing (see arguments in §1). Void-related issues (and problems with other limit values) would of course have been less likely detected with a purely random strategy. We conjecture that our results generalize, modulo the other threats to validity from §3. It is also important to point out that a significant proportion of specification errors are due to void-related issues, which are scheduled to go away as the new versions of Eiffel, starting with 6.2 (Spring 2008), implement the “attached type” mechanism [33]. This removes the problem by making non-voidness part of the type system and catches violations at compile time rather than run time.

Second, the results presented here can help reveal the effectiveness of an automated testing tool. In particular, we can see that AutoTest is good at finding faults, but it is not good at finding all faults. This highlights the need for further research into automated testing tools and their effectiveness in detecting faults.

As to whether it is useful or interesting to detect and analyze faults in contracts, one must keep in mind that most often the same person writes both the contract and the body of a routine. A fault in the contract signals a mistake in this person’s thinking just as a fault in the routine body does. Once the routine has been implemented, client programmers who want to use its functionality from other classes look at its contract to understand under what conditions the routine can be called (expressed by its precondition) and what the routine does (the postcondition expresses the effect...
of calling the routine on the state). Hence, if the routine’s contract is incorrect, the routine will most likely be used incorrectly by its callers, which will produce a chain of faulty routines. The validity of the contract is thus as important as the correctness of the implementation.

The existence of contracts embedded in the software is a key assumption both for the proposed fault classification and for the automated testing strategy used. We do not consider this to be too strong an assumption because it has been shown [9] that programmers willingly use a language’s integrated support for Design by Contract, if available. For languages lacking such features and having only rudimentary support for checking conditions at runtime in the form of the assert mechanism, the situation is different: programmers using these languages are indeed resistant towards including assertions in their code. Nevertheless, for such languages approaches [16, 24] have been developed for inferring contracts from executions of the system.

The evaluation of the performance of random+ testing performed here always considers the faults that AutoTest finds over several runs, using different seeds for the pseudo-random number generator. In previous work [12] we have shown that random+ testing is predictable in the number of faults that it finds, but not in the kind of faults that it finds. Hence, in order to reliably assess the types of faults that random+ testing finds, it is necessary to sum up the results of different runs of the tool.

In addition to pointing out strengths and weaknesses of a certain testing strategy, a classification of repeatedly occurring faults based on the cause of the fault also brings insights into those mechanisms of the programming language that are particularly error-prone. For instance, faults due to wrong export status of creation procedures show that programmers do not master the property of the language that allows creation procedures to be exported both for object creation and for being used as normal routines.

### 4.6 Threats to validity

The biggest threat to the generalization of the results presented here is the small size of the set of manually tested classes, of the analyzed user bug reports, and of the group of human testers participating in the study. In particular, in this paper, not all techniques were applied to the same code base (manual testing was not applied to all classes of the base library), and we did not directly compare bug reports to manual tests. We intend to more homogeneously expand this study to larger and more diverse code bases.

Like the quality of the implementation code, the quality of the oracle, i.e., the contracts, will of course influence our results. With a larger code base, a respective threat to the validity of generalizing our results could be countered.

As explained in §4.1, we only had access to bug reports submitted by users for the EiffelBase library. Naturally, these are not all the faults found in field use, but only the ones that users took the time to report. Interestingly, for all but one of these reports the users set the priority to either “medium” or “high”; the severity, on the other hand, is “non-critical” for 7 of the reports and either “serious” or “critical” for the others. This suggests that even users who take the time to report faults only do so for faults that they consider important enough.

As we could not perform the study with professional testers, we used bachelor and master students of computer science; to strengthen the incentive for finding as many faults as possible, we ran this as a competition. We did not instruct the students to follow any particular manual testing strategy (such as coverage-oriented testing, limit-value testing, etc.) nor did we discourage them from doing so. In other words, the students had complete freedom in choosing if they wanted to apply a certain strategy or none at all, since the purpose of the experiment was to study how manual testing in general compares to random+ testing.

A further threat to generalization is due to the peculiarities of the random testing tool used. AutoTest implements one particular algorithm for random testing and the results described here would probably not be identical for other approaches to the random testing of OO programs (e.g., [13]). In particular, we make use of extreme values to initialize the object pool (§2). While void objects are rather likely to occur in practice, extreme integer values are not. In other words, the approach, as mentioned, is not entirely random.

Also as noted, compile-time removal of void-related errors will affect the results, for ISO Eiffel and other languages that have the equivalent of an “attached type” mechanism (including Spec# [4]).

Another source of uncertainty is the assignment of defects to a classification. Finding a consistent assignment among several experts is difficult [26]. In our study, one person was assigned to this task. While this yields consistency, running the experiment with a different person might produce different results.

Finally, the programming language used in the study, Eiffel, also influenced the results. As explained in §4.5, a few of the fault categories are closely related to the language mechanisms that are misused or that allow the fault to occur. This is to be expected in a classification of software faults based on the cause of the faults.

The fault classification is inherently object-oriented. Although some fault categories may appear in non-object-oriented code too, the distribution and nature of faults is most likely very different in non-object-oriented systems than in the code examined in our study, so we do not believe that the results are generalizable outside of object-oriented systems. Moreover, there is of course a chance that other classification schemes would lead to different results—which would allow different assessments of the three strategies.
5 Related work

Many fault classification models have been proposed in the past [10, 1, 31, 21, 6, 37]. This includes the Orthogonal Defect Classification (ODC) [10] whose main point is to combine two different classifications, defect types and defect triggers. In a sense our classification is an ODC in itself but our classification of defect types is finer while the defect location is simpler than defect triggers. The IEEE classification [1] aims at building a framework for a complete characterization of the defect. It defines 79 hierarchically organized types that are sufficient to understand any defect. In our case using such categories would not have helped because they do not reflect the particular constructs of contract-enabled languages. Ma et al. [32] define fault categories for Java programs and relate them to mutation operators. It is unclear how the mapping from failures to these fault categories could be done automatically, and the categories do not take into account contracts. Lutz [31] describes a safety checklist that defines categories of possible errors in safety-critical embedded systems. The classification probably most similar to ours is that by Basili et al. [5, 29, 41], organized in two dimensions: whether the fault is an omission or a commission fault, and to which of 6 possible types it belongs. Our classification takes into account specifications (contracts) and is more fine-grained.

Bug patterns (e.g., [2, 27]) are also related to our work. Allen [2] defined 14 types of defects in Java programs. Our approach has to cope with different constructs and thus defines categories adapted to Eiffel programs, taking into account contracts and multiple inheritance.

Several studies compare different testing strategies by evaluating their respective failure-triggering capabilities. Random tests have been compared to partition testing both theoretically and empirically [22, 40, 15, 23], and the effectiveness of model-based testing has been studied [38, 25, 7]. These studies do not take into consideration a classification of faults which, among other things, led us to conduct the experiment presented here.

Numerous other studies have compared structural and functional testing strategies as well as code reading (among others, [18, 5, 29, 41]). None of these studies compares manual testing to automated techniques. Our study compares random+ testing with manual testing and user bug reports; as far as we know, this is the first time that these three methods of identifying software faults are correlated. Like most of the earlier comparative studies, the results highlight the complementarity of different techniques.

6 Conclusions

One of the main goals of this work is to understand if different ways of detecting faults detect different kinds of faults. The question is of high practical importance: which testing strategy should be applied under which circumstances? A further motivation was the conjecture that a reason for the inconclusiveness of earlier comparative studies is that the number of detected faults alone is too strong an abstraction for comparing testing strategies.

In this paper we examined the kind of faults that random+ testing finds, and whether and how these differ from faults found by human testers and by users of the software. Our experiments suggest that these three strategies for finding software faults have different strengths and applicability. None of them subsumes any other in terms of performance. Random+ testing with AutoTest has the advantage of being completely automatic. The experiments presented here as well as in earlier work [11, 12] show that the tool indeed finds a high number of faults in little time. Humans, however, find faults that AutoTest misses. This is shown both by the examined user bug reports and by asking testers to test some code on which AutoTest was run, and by subsequently comparing the results. This last experiment also proved that AutoTest finds faults that testers miss. The conclusion is that random+ tests should be used alongside with manual tests. Given earlier results on comparing different QA strategies, this is not surprising, but we are not aware of any systematic studies that showed this for random testing. We discussed threats to generalizing these results in §4.6.

The results of research into randomly testing Eiffel programs can also be used for investigating the benefits of using contracts and how to improve contracts, possibly based on specification patterns. Future work in this direction will require performing more experiments of the kind presented in this paper, adjusting the classification, and comparing concrete testing strategies such as partition-based testing or usage-profile-based testing rather than the — admittedely underspecified — “manual testing strategy.”

Our analysis is based on a classification of faults that is not specific to one particular application domain. For specification faults, it covers typical problems with pre- and postconditions and invariants that are too weak, for example by not taking extreme values into account, or too strong. For implementation faults, it covers a few general problems such as missing cases or infinite loops, and some problems that relate to the specifics of Eiffel. We do not assert that our classification is complete or the only possible one; it is the result of analyzing the faults that we encountered. We believe that this classification, or some variant of it, can be used for future experiments on comparing strategies for finding faults.

As for any case study, the applicability of the results is limited: we consider three approaches for finding software faults and investigate them for Eiffel code equipped with contracts. Still, the case study presented here provides a foundation for other researchers to build upon.
