IV. SUMMARY

The spatiotemporal orchestration of proliferation and growth is of paramount importance for the maintenance of distinct cell layers and tissue morphogenesis in plants. Single cell layers are maintained by proliferative cell divisions with the cell division plane stereotypically oriented in a strictly anticlinal fashion. This is referred to as planar growth. Disturbance of this process leads to periclinal or oblique divisions, which in turn introduce new cell layers and can result in tumor formation. The molecular mechanisms underlying planar growth control are poorly understood. Arabidopsis ovule integuments were shown to be excellent model tissues to study planar growth. Major advantages are their good accessibility, the relatively simple structure of the four integumental layers, and the high numbers of ovules per pistil. The AGCVIII kinase UNICORN (UCN) was shown to be of critical importance in the suppression of ectopic growth. The *ucn-1* mutant exhibits aberrant cell divisions in the ovule integuments eventually resulting in protrusion formation (Schneitz et al. 1997, Enugutti et al. 2012). Similar alterations can be observed in petals and stamens of *ucn-1* mutants (Enugutti et al. 2012). UCN was shown to suppress protrusion formation in integuments by directly repressing the KANADI transcription factor ABERRANT TESTA SHAPE (ATS) (Enugutti et al. 2012, Enugutti and Schneitz 2013). Other molecular components participating in the *UCN* signaling pathway have not been identified so far.

In this study, I present evidence that the two Arabidopsis 3-PHOSPHOINOSITIDE DEPENDENT KINASES 1 (PDK1s) are components, which need to be repressed in the *UCN*-mediated signaling pathway. PDK1 is a central regulator of AGC kinases in animals and at least for some plant AGC kinases. Genetic analyses of *ucn pdk1* double mutants reveal that UCN acts as a negative regulator of both PDK1s. Interestingly, overexpression of either *PDK1* leads to *ucn-1*-like phenotypes with respect to integuments and petals. Furthermore, I demonstrate that both PDK1 proteins interact directly with UCN in vitro and in vivo.

My further findings indicate that PDK1 is able to phosphorylate UCN and vice versa. PDK1 is able to activate UCN through phosphorylation, and subsequent UCN-mediated PDK1 phosphorylation results in decreased PDK1 activity, which in turn is crucial for the ectopic growth suppression in ovule integuments and petals. Direct PDK1 suppression by another AGC kinase is a novel and unique feature in AGC kinase regulation. While ATS is only involved in the ovular aspect of *UCN* signaling, PDK1 plays a more global role. UCN mediated repression of ATS and PDK1 leads to the question about the relation between ATS and PDK1. I can demonstrate that PDK1 and ATS

do not interact directly in vivo most likely due to their spatial separation (ATS in the nucleus, PDK1 in the cytosol/at the plasma membrane). In addition, I propose a model for integument growth, in which ATS induces the expression of a gene whose resulting protein is a downstream target of PDK1.

V. ZUSAMMENFASSUNG

Die räumlich-zeitliche Koordination von Proliferation und Wachstum ist von entscheidender Bedeutung für die Aufrechterhaltung einzelner Zellschichten und die Gewebemorphogenese in Pflanzen. Einzelzellschichten werden durch proliferative Zellteilungen aufrechterhalten, wobei die Zellteilungsebene strikt antiklin orientiert ist. Dies wird als planares Wachstum bezeichnet. Eine Störung dieses Prozesses führt zu periklinen oder schrägen Zellteilungen, die wiederum neue Zellschichten einführen und zur Tumorbildung führen können. Die molekularen Mechanismen, die der planaren Wachstumskontrolle zugrunde liegen, sind nur wenig verstanden. Die Integumente der Samenanlage von *Arabidopsis* sind ausgezeichnete Modellgewebe, um planares Wachstum zu studieren. Große Vorteile sind die gute Zugänglichkeit und die relativ einfache Struktur der vier Integumentschichten, sowie die hohe Anzahl an Samenanlagen pro Fruchtknoten. Es wurde gezeigt, dass die AGCVIII-Kinase UNICORN (UCN) von entscheidender Bedeutung für die Unterdrückung ektopischen Wachstums ist (Schneitz et al. 1997, Enugutti et al. 2012). Die *ucn-1*-Mutante zeigt abweichende Zellteilungen in den Integumenten, was schließlich zu tumorähnlichen Auswüchsen führt. Ähnliche Veränderungen können in den Petalen und Stamina beobachtet werden (Enugutti et al. 2012). Es wurde gezeigt, dass UCN die Bildung der Auswüchse in den Integumenten durch direkte Repression des KANADI-Transkriptionsfaktors ABERRANT TESTA SHAPE (ATS) unterdrückt (Enugutti et al. 2012, Enugutti und Schneitz 2013). Andere am UCN-Signalweg beteiligte molekulare Komponenten wurden bislang nicht identifiziert.

In dieser Arbeit zeige ich, dass die beiden 3-Phosphoinosotid-abhängigen Kinasen (PDK1) Komponenten sind, die im UCN-vermittelten Signalweg reprimiert werden müssen. Genetische Analysen von *ucn-pdk1*-Doppelmutanten zeigen, dass UCN als negativer Regulator beider PDK1-Proteine fungiert. Interessanterweise führt die Überexpression beider *PDK1*-Gene unabhängig voneinander zu einem *ucn-1*-ähnlichen Phänotypen in Bezug auf die Integumente und Petalen. PDK1 ist ein zentraler Regulator von AGC-Kinasen in Tieren und zumindest für einige pflanzliche AGC-Kinasen. Darüber hinaus zeige ich, dass beide PDK1-Proteine *in vitro* und *in vivo* direkt mit UCN interagieren.

Meine Ergebnisse zeigen, dass PDK1 UCN phosphorylieren kann und umgekehrt. PDK1 ist in der Lage UCN durch Phosphorylierung zu aktivieren, und die darauffolgende UCN-vermittelte PDK1-Phosphorylierung führt zu einer verminderten PDK1-Aktivität, was wiederum entscheidend für die Suppression ektopischen Wachstums in den Integumenten und Petalen ist. Die direkte

PDK1-Unterdrückung durch eine andere AGC-Kinase ist ein neues und einzigartiges Merkmal der AGC-Kinase-Regulation. Während ATS nur in der Samenanlage in den *UCN*-Signalweg involviert ist, spielt PDK1 im Vergleich eine globalere Rolle. Die *UCN*-vermittelte Repression von ATS und PDK1 führt zu der Frage nach der Beziehung zwischen ATS und PDK1. Ich kann zeigen, dass PDK1 und ATS *in vivo* nicht miteinander interagieren, höchstwahrscheinlich auf Grund ihrer räumlichen Trennung (ATS im Zellkern und PDK1 im Cytosol/an der Plasmamembran). Zusätzlich schlage ich ein Modell für das Wachstum von Integumenten vor, bei dem ATS die Expression eines Gens induziert, deren resultierendes Protein nachgeordnetes Ziel von PDK1 ist.

1 INTRODUCTION

1.1 Tissue morphogenesis and organogenesis in plants

Plant organogenesis occurs mostly in a post-embryonal fashion. In contrast to animals, the plant embryo develops into a seedling with simple architecture. Aboveground lateral organs ultimately originate from the shoot apical meristem (SAM), which gives rise to leaves, shoot branches and, once switched to the reproductive phase of the plant's life cycle, eventually to flowers. The spatiotemporal coordination of cell elongation and proliferation is of crucial importance for the maintenance of distinct cell layers and tissue morphogenesis.

1.1.1 Pattern formation during floral development

The outgrowth of primordia and the determination of organ identity is strictly controlled. The SAM develops into an inflorescence meristem (IM), producing floral primordia that develop into floral meristems (FMs), from which floral organs, such as sepals, petals, stamens and carpels, finally arise ((Miksche and John 1965, Coen and Meyerowitz 1991), Figure 1-1, a). Shoot and floral meristems are organized into several distinct zones. The central zone (CZ) comprises infrequently dividing stem cells that are innately undifferentiated. The organizing center (OC) beneath the stem cells supplies a cell niche necessary for stem cell induction and maintenance. At the flanks of the CZ, progeny of the stem cells ends up in the peripheral zone (PZ) where cell division occurs at higher rates and floral organs arise (Figure 1-1, b). Moreover, the meristems consist of three distinct cell layers (Satina et al. 1940) that are maintained by certainly oriented cell division. The two outermost layers, i.e. L1 (epidermal) and L2 (sub-epidermal), divide strictly perpendicular to the surface of the meristem (anticlinal cell division), the innermost L3 core divides in an apparently rather random fashion (Figure 1-1, b). Organ formation is triggered by local auxin maxima in the L1 of the PZ (Reinhardt et al. 2000, Reinhardt et al. 2003, Heisler et al. 2005). Auxin is produced throughout the meristem (Pinon et al. 2013) and actively redistributed in a PIN-FORMED (PIN)-dependent polar fashion to the sites of organ initiation (Grünwald and Friml 2010). The PINs are activated through phosphorylation by plasma membrane (PM)-associated AGCVIII kinases, such as PINOID (PID) and D6 PROTEIN KINASE (D6PK) (Zourelidou et al. 2014). Basipetal reorganization

INTRODUCTION

of the PINs leads to the formation of an auxin sink, and auxin accumulation in the interior of the initiated floral primordium (Heisler et al. 2005, Bayer et al. 2009).

Figure 1-1 Overview of early flower development, the ABCE, and the quartet model of floral organ patterning.

(a) Scanning electron micrograph of an Arabidopsis shoot apical meristem with indicated floral primordia of different stages (youngest P1 to oldest P7). A sepal (se) primordium is shown in P7. (b) Confocal micrograph of a mid-optical vertical section of a stage 3 floral meristem. Sepal (se) primordia at the flanks are indicated. CZ, central zone; PZ, peripheral zone; cell layers L1 – L3 are indicated. Scale bars: 10 μ m. (c) Cartoon depicting floral fate initiation by the interplay of auxin, MP, LFY, and GA. (a – c) from Vaddepalli et al. (2015). (d) The ABCE model of floral organ patterning, adapted from Krizek and Fletcher (2005). Arabidopsis WT flowers consist of four whorls. In the first whorl, class A activity confers sepal (se) identity, petal (pe) identity is conferred by class A and B activity, class B and C activity confers stamen (st) identity, and carpel (ca) identity is conferred by class C activity. Class A and C repress each other as indicated. Loss of class A identity in *apetala1* (*ap1*) or *ap2* mutants leads to expansion of class C activity, and transforms se into ca and pe into st. Loss of class B activity in *ap3* or *pistillata* (*pi*) mutants transforms pe into se and st into ca. Flowers of the *agamous* (*ag*) mutant lacking class C activity consist of reiterative patterns of se, pe, pe, se by expansion of class A activity and loss of floral determinacy. The *sepallata1 – 4* (*sep1,2,3,4*) quadruple mutant consists of reiterations of leaf-like (le) organ whorls. Loss of class E activity results in impaired class A, B, C functions and loss of floral determinacy. *SEEDSTICK* (*STK*), *SHATTERPROOF1* (*SHP1*) and *SHP2* were identified as ovule-specifying factors (D function). (e) Floral quartet model, adapted from Theißen et al. (2016). Floral organ identity is specified by the formation of organ-specific tetrameric complexes, which bind to two adjacent *cis*-regulatory elements of the DNA.

As shown in Figure 1-1c, the auxin response transcription factor (TF) MONOPTEROS (MP) activates several genes, including the transcription factors LEAFY (LFY), AINTEGUMENTA (ANT) and AINTEGUMENTA-LIKE6/PLETHORA3 (AIL6/PLT3), in an auxin-dependent fashion (Yamaguchi et al. 2013). In turn, LFY activates a central regulator of flower identity, the MADS-domain transcription factor APETALA1 (AP1) (Wagner et al. 1999), and represses the negative effect of gibberellic acid (GA) by positively regulating EUI-LIKE P450 A1 (ELA1) (Yamaguchi et al. 2014). Moreover, LFY, ANT and AIL6 share overlapping functions in floral fate determination (Weigel et al. 1992, Weigel and Nilsson 1995, Krizek 1999, Mizukami and Fischer 2000, Krizek and Eaddy 2012). The initiated FM is organized through a negative feedback loop (Fletcher et al. 1999, Brand et al. 2000). *WUSCHEL* (*WUS*), a homeodomain TF gene, is expressed in the OC and the *WUS* protein moves to the CZ, where it specifies stem cell fate in a non-cell autonomous manner (Yadav et al. 2011). *WUS* directly represses expression of the receptor-like kinase (RLK) gene *CLAVATA1* (*CLV1*), and activates its own negative regulator, the signal peptide *CLAVATA3* (*CLV3*) (Busch et al. 2010, Yadav et al. 2011). Furthermore, *WUS* affects cytokinin signaling (Leibfried et al. 2005), and represses several differentiation-promoting TFs (Yadav et al. 2013).

Floral organ identity is conferred through the combinatorial action of a set of transcription factors, which except for *APETALA2* (*AP2*) belong to the MIKC-type MADS-domain TFs (Irish 2010). The ABCE-model in Figure 1-1d depicts the interplay between those TFs in floral organ

specification. *APETALA1* (*AP1*) and *AP2* provide class A function, B function is mediated by *AP3* and *PISTILLATA* (*PI*), and C function by *AGAMOUS* (*AG*) (Yanofsky et al. 1990, Mandel et al. 1992, Jack et al. 1992, Goto and Meyerowitz 1994, Jofuku et al. 1994). *SEEDSTICK* (*STK*), *SHATTERPROOF1* (*SHP1*) and *SHP2* mediate class D function for ovule identity (Angenent and Colombo 1996, Favaro et al. 2003, Pinyopich et al. 2003). As shown in Figure 1-1e, The *SEPALLATA* genes *SEP1*, *SEP2*, *SEP3* and *SEP4* contribute to the identity of all floral organs (Pelaz et al. 2000, Pelaz et al. 2001, Ditta et al. 2004). Class A and E activity results in sepal (*se*) identity, petals (*pe*) are determined by the activity of classes A, B, E. Stamina are specified by B, C and E activity, C and E specify carpels and C, D, and E specify ovules (reviewed in Theißen (2001), Krizek and Fletcher (2005), Ó'Maoiléidigh et al. (2014), Theißen et al. (2016)).

1.1.2 Ovule development

The plant's life cycle is alternating between a haploid (gametophyte) and a diploid generation (sporophyte). Meiosis in plants generates haploid spores, which undergo differentiation and proliferation to give rise to the gametophytes. In turn, the gametophytes produces haploid gametes. The life cycle is completed by the fusion of egg cell and sperm cell producing the sporophyte (Raven et al. 1992). The ovule represents the major female reproductive organs in spermatophytes, and consists in principle of three functional domains: the nucellus containing the female gametophyte, the chalaza that gives rise to the integuments eventually surrounding the nucellus, and a stalk, called funiculus, representing the connective tissue to the placenta. Since the ovule contains the egg cell, and upon fertilization, it develops into seeds, the understanding of the molecular mechanisms controlling ovule development is of pivotal importance. Ovule ontogenesis has been well described during the last decades of research (Mansfield and Briarty 1991, Robinson-Beers et al. 1992, Modrusan et al. 1994, Schneitz et al. 1995, Schneitz et al. 1997, Grossniklaus and Schneitz 1998, Drews et al. 1998, Schneitz et al. 1998, Gasser et al. 1998, Schneitz 1999, Truernit and Haseloff 2008, Cucinotta et al. 2014), and a staging system has been conceived (Schneitz et al. 1995).

INTRODUCTION

The ovule originally arises as a finger-like protuberance from the placental tissue (stages 1-I/II of ovule development, stages according to Schneitz et al. (1995)). At the distal end of the primordium (nucellus), a single hypodermal cell develops into the megaspore mother cell (MMC) (stage 2-I). Subsequently, the MMC undergoes meiosis in order to form a tetrad of haploid megaspores (stage 2-V). The three distal ones degenerate resulting in a single viable megaspore that gives rise to a multicellular embryo sac or female gametophyte (including the egg cell). During stages 2-II/III an outer and an inner integument initiate, which are of epidermal origin and will form two sheets each consisting of two layers (an adaxial and an abaxial cell layer), and eventually enclosing the nucellus completely. Embryo sac formation within the nucellus and integument maturation take place during stages 3-I to 3-VI. As described before, only the most proximal megaspore survives and forms the embryo sac comprising seven cells (three antipodal cells, a central cell and an egg cell, and two synergids). The asymmetric growth of the integuments determines the typical curvature and therefore the final amphitropous configuration of the ovule (Figure 1-2). The vasculature within the funiculus has emerged by the end of stage 3. The last main stage 4 (stages 4-I to 4-V) involves fertilization, as well as initial parts of endosperm development and embryogenesis.

Figure 1-2
Simplified cartoon depicting two stages of ovule development.

(a) Ovule at stage 2-V (Schneitz et al. 1995). Two layers of each, inner and outer integument, initiated from the chalazal flanks and continue growth to eventually surrounding the nucellus. (b)

Mature ovule displaying the typical amphitropous shape. Integuments envelop the embryo sac. *c* chalaza, *f* funiculus, *n* nucellus, *i.i.* inner integument, *o.i.* outer integument, (*ab*) abaxial, and (*ad*) adaxial cell layer. Figure from Enugutti et al. (2013), adapted from Truernit and Haseloff (2008).

1.1.3 Arabidopsis ovules as model systems for organ development

Due to their good accessibility, their relatively simple structure and the high number of developmentally independent organs (~ 50 ovules per WT pistil), Arabidopsis ovules are an excellent model system to study organ development, and their integuments represent excellent tissues to investigate planar growth. The ovule comprises two integuments each consisting of two layers eventually giving rise to the seed coat. An initial asymmetric division at the flanks of the chalazal region of the young ovule is followed by subsequent symmetric and strictly anticlinal cell division events generating the four single cell layers of integuments. In the last stage (3-VI) of ovule development before fertilization cells of the adaxial inner integument undergo periclinal divisions to give rise to an additional single cell layer, the inner integument 1' (ii1') (Schneitz et al. 1995). 35% of Col-0 and 70% of Wassilewskija ovules exhibit a sixth integument cell layer (ii1''), which derives from additional periclinal divisions in ii1' at stage 3-VI/4-I transition (Coen et al. 2017). Mutants impaired in correct cell division orientation can help to elucidate the underlying molecular mechanisms coordinating planar growth. Initially discovered in an EMS screen for identifying ovule mutants (Schneitz et al. 1997), *UNICORN* (*UCN*, *At1g51170*) was found to encode for an active AGCVIII protein kinase suppressing aberrant cell divisions in integuments (confer Figure 1-3), and other lateral organs by directly repressing the KANADI TF ABERRANT TESTA SHAPE (ATS) (Enugutti et al. 2012, Enugutti et al. 2013).

1.1.4 Cell division plane and planar growth

Planar growth crucially depends on cell divisions and molecular mechanisms correctly orienting the division plane relative to the surrounding cell layers. In contrast to animal cells, plant cells are surrounded by a rigid cell wall and therefore immobile. Novel cell layers need to be initiated by defined orientations of the division planes (parallel or oblique to the surface of the tissue). The same holds true for the maintenance of distinct cell layers but, in contrast, the division plane needs to be oriented perpendicular to the surface. This strictly anticlinal and symmetric division behavior, in which periclinal and oblique divisions are repressed, leads to the propagation of a certain cell layer, for which cell division is oriented within the plane of the layer (planar growth) (Tilney-Bassett 1986). In the last decade, impressive progress in understanding the control of asymmetric cell division has been made (Abrash and Bergmann 2009, Petricka et al. 2009, De Smet and Beeckman 2011). The division plane orientation in symmetrically dividing cells can be predicted by mathematical models involving cytoskeleton dynamics and cell geometry (Besson and Dumais 2011). Cell geometry and the behavior of adjacent cells lead to distinct tensile stress patterns, and cortical microtubules align along maximal tensile stress in cell walls (Hamant et al. 2008, Besson and Dumais 2011, Sampathkumar et al. 2014). The future plane of division correlates with the orientation of the preprophase band (PPB), which consists of actin filaments, the ring of aligned cortical microtubules, organelles, and various proteins associated with organelles or the cytoskeleton appears at the position of the division plane. The PPB emerges in G2 phase of the cell cycle as a broad band of microtubules, and narrows during prophase by actin-mediated connection of adjacent microtubules (Mineyuki and Palevitz 1990, Takeuchi et al. 2016). It remains unknown if the PPB itself actively determines the division plane or if yet unidentified signals locate the PPB to the position of the later division plane. It was shown recently, that the PPB controls the robustness of division orientation by increasing the accuracy of spindle adjustment (Ambrose and Cyr 2008, Schaefer et al. 2017). Furthermore, the PPB positioning is directly dependent on the position of the nucleus within the mother cell (Murata and Wada 1991, Mineyuki et al. 1991). In late prophase, the nuclear membrane disassembles and acentriolar spindle formation occurs. Subsequently, the chromosomes align at the division plane in metaphase, and the central spindle emerges in anaphase at the position of the metaphase chromosomes. Detailed information is reviewed in, e.g. Lipka et al. (2015), Smertenko et al. (2017).

1.1.5 Growth control and polarity determination: A concert of transcription factors

The development of lateral organs is characterized by a distinct abaxial-adaxial polarity. Removal of leaf primordia from the meristem leads to the development of radial abaxialized structures suggesting that signals from the meristem are required for abaxial-adaxial polarity, and that abaxial cell fate might be the default state (Sussex 1954). Antagonistic effects between class III HOMEODOMAIN LEUCINE-ZIPPER (HD-ZIP III) and KANADI (KAN) transcription factors, resulting in polar YABBY expression, control abaxial-adaxial lateral organ polarity. In *Arabidopsis*, members of *KAN* and *YABBY* gene families promote abaxial cell fate (Sawa et al. 1999, Siegfried et al. 1999, Eshed et al. 1999, Eshed et al. 2001), whereas members of the HD-ZIP III gene family, such as *PHABULOSA (PHB)*, *PHAVOLUTA (PHV)*, *CORONA (CNA)* and *REVOLUTA (REV)*, promote adaxial cell fate (McConnell and Barton 1998, McConnell et al. 2001, Emery et al. 2003, Kelley et al. 2009). Loss-of-function alleles of HD-ZIP III (*PHB*, *PHV*) result in radial abaxialized cotyledons (Emery et al. 2003), and gain-of-function alleles in radial adaxialized leaves (McConnell and Barton 1998, McConnell et al. 2001). In contrast, the situation for *KAN* is the opposite: gain-of-function alleles lead to radial abaxialization of organs (Eshed et al. 2001, Kerstetter et al. 2001). Hence, the conversion to all adaxial or all abaxial fates leads to a loss of lamina expansion because the juxtaposition of these two domains is of crucial importance for lamina development. Disruption of the abaxial-adaxial polarity can lead to ectopic outgrowth ((Eshed et al. 2001, Kerstetter et al. 2001), see section 1.3.2). The restriction of the TFs to their domains is mediated by micro RNA (miRNA) activity (such as miRNA 165/166) (Reinhart et al. 2002, Rhoades et al. 2002, Tang et al. 2003, Juarez et al. 2004, Zhong and Ye 2007).

In *Arabidopsis*, the KANADI TF *ATS* is restricted to ovule integuments. *ATS* is expressed at the boundary of the two integuments during integument initiation (Figure 1-3, F + I), and expression restricts to the abaxial layer of the inner integument later during integument growth (McAbee et al. 2006). Functional *ATS* is critical for proper ovule development by maintaining the boundary between the two integuments, for promoting laminar growth of the inner integument (McAbee et al. 2006), and acts in concert with *PHB/PHV/CNA* in order to regulate integument morphogenesis (Kelley et al. 2009). Loss-of-function leads to inherent fusion of the outer and the inner integument, and thus, to aberrant seed coat formation (Leon-Kloosterziel et al. 1994, McAbee et al. 2006). In contrast, loss of *KAN1* and *KAN2* leads to the disruption of the outer integument (Eshed et al. 2001, McAbee et al. 2006). These genes act redundantly in the outer

integument but, in contrast to *ATS*, are not only involved in integument development (Leon-Kloosterziel et al. 1994, Eshed et al. 2001, McAbee et al. 2006). *KAN* control auxin signaling in concert with AUXIN RESPONSE FACTOR (ARF) proteins (Pekker et al. 2005). Especially *ETTIN* (*ETT/ARF3*) plays a pivotal role in ovule development (Sessions et al. 1997, Kelley et al. 2012). *ETT* forms a functional complex with *ATS*, which accumulates in the abaxial layer of the inner integument and modifies auxin action by negatively regulating *PIN1* expression (Kelley et al. 2012). Moreover, evidence was provided that *ETT* forms a similar complex with other *KAN* transcription factors (Kelley et al. 2012).

Another important player in outer integument development is the YABBY TF INNER NO OUTER (*INO*). *ATS* and *REV* together restrict *INO* expression to the abaxial layer of the outer integument and thereby outer integument growth (Kelley et al. 2009). Loss-of-*INO*-function mutants depict outer integument initiation but no growth, and therefore lacking ovule curvature (Baker et al. 1997, Villanueva et al. 1999). Loss of the outer integument resulting in loss of curvature suggests that the outer integument itself imposes curvature resulting in the final amphitropous configuration.

1.2 Protein kinases in plant development and physiology

Phosphorylation and dephosphorylation of proteins play important roles in all aspects of the life cycle of plants. Thereby, protein kinases (PK) accomplish the process of protein phosphorylation whereas protein phosphatases catalyze protein dephosphorylation. Phosphorylation and dephosphorylation represent quick and reversible posttranslational protein modifications leading to conformational changes, translocation and/or changes in substrate activity. Protein phosphorylation is highly specific, strictly controlled, and enables regulation, amplification and interconnection of molecular signals (Pawson and Scott 2005). If the substrate of a protein kinase itself is a protein kinase, the initial phosphorylation signal can lead to the activation or inactivation of many effector proteins, and hence, activation of a complete signaling cascade can occur (Pawson and Scott 2005). Therefore, PKs are crucial for plant development and adaption to changing environmental conditions. In *Arabidopsis*, more than 1000 genes encode protein kinases (kinome), which comprises 4% of all protein-encoding genes (Zulawski et al. 2014), whereas the human kinome only represents 2% of the protein-encoding genes (Manning et al. 2002). Kinases have been subdivided in several major phylogenetic groups. The receptor-like

kinases (RLK), including the large family of transmembrane leucine-rich-repeat receptor-like kinases (LRR-RLK), and the membrane-associated receptor-like cytoplasmic kinases (RLCK), represent about 60% of all kinases (Zulawski et al. 2014, Zulawski and Schulze 2015). This high abundance of RLKs is a unique feature for the plant kingdom. In addition, the following plant kinase families can be distinguished: CMGC kinases, named after their members cyclin-dependent kinases (CDK) and mitogen-activated protein kinases (MAPK); Ca²⁺/Calmodulin (CaM)-dependent kinases (CaMK); STE kinases (homologs of *S. cerevisiae* sterile kinase); and AGC kinases, named after the cAMP-dependent protein kinase A, cGMP-dependent protein kinase G and the phospholipid-dependent protein kinase C families (PKA, PKG, PKC) (Champion et al. 2004, Dissmeyer and Schnittger 2011, Zulawski and Schulze 2015). Additionally, other kinases are present, which do not fall into one of the above-mentioned families. For instance, AURORA kinases that are involved in the regulation of asymmetric cell divisions via phosphorylation of histone 3 during mitosis (Demidov et al. 2009, Kawabe et al. 2005, Kurihara et al. 2006, Van Damme et al. 2011), and the TARGET OF RAPAMYCIN (TOR) kinase, which represents an essential regulator of nutritional, stress-related and developmental pathways (Menand et al. 2002, Ren et al. 2012).

1.2.1 AGC kinases and plant development

Plants possess the same basic AGC kinase subfamilies (PDK1, S6K, and NDR) as other eukaryotes but they do not encode for the typical AGC kinases, such as PKA and PKC, involved in the control of cell expansion, proliferation and polarity in fungi and animals. The Arabidopsis genome encodes 39 AGC kinases, 23 of which belong to the plant specific AGCVIII subfamily (Figure 1-4). Several of those are involved in hormone signaling. PID, D6PK, WAG1, WAG2, and the blue light receptors PHOTOTROPIN1 (PHOT 1) and PHOT2 are involved in auxin signaling (Santner and Watson 2006, Cho et al. 2007, Zhang et al. 2009, Dhonukshe et al. 2010, Willige et al. 2013, Zourelidou et al. 2014, Weller et al. 2017). WAG2 is also involved in gibberellic acid (GA) signaling (Willige et al. 2012), and S6K plays a role in abscisic acid (ABA) and auxin signaling (Mahfouz et al. 2006, Turck et al. 2004). Furthermore, OXIDATIVE SIGNAL INDUCIBLE 1 (OXI1) and AGC2-2/OXI2 were shown to have functions in biotic and abiotic stresses downstream of 3-PHOSPHOINOSITIDE-DEPENDENT KINASE 1 (PDK1) (Anthony et al. 2006, Camehl et al. 2011, Howden et al. 2011). Enugutti et al. (2012) showed that the AGCVIII kinase UNICORN (UCN) suppresses ectopic growth in Arabidopsis ovule integuments by directly repressing the KANADI transcription factor ATS through phosphorylation. In general, AGC kinases become activated by phosphorylation of the T-loop within the activation segment. In mammalian systems, PDK1 acts as the master regulator of

AGC kinase activity by activating various AGC kinases through phosphorylation of their T-loops. Other AGC kinases, including PDK1, are capable of auto-activation through auto-phosphorylation (Rademacher and Offringa 2012). Two Arabidopsis genes encoding for PDK1 (PDK1.1 and PDK1.2) have been identified. Although they were shown to be involved in the in vitro activation of a minimum of 16 AGC kinases, biological relevance of PDK1-mediated activation could not be demonstrated (Bögre et al. 2003, Anthony et al. 2004, Zegzouti et al. 2006a, Zegzouti et al. 2006b)

1.2.2 PDK1 – master of the AGCs?

PDK1 genes are present throughout eukaryotes (Zegzouti et al. 2006a, Zegzouti et al. 2006b,

Figure 1-4 Phylogenetic tree of the Arabidopsis AGC kinase family.

The AGCVI subfamily contains the two S6 KINASES (S6K1 and S6K2), the AGCVII subfamily has eight members related to the nuclear Dbf2-related kinase (NDR1 – NDR8), and the AGC other group contains four members, which are named after one member INCOMPLETE ROOT HAIR ELONGATION (IRE, IRE-H1, IRE3, and IRE4). The two PDK1s are grouped in the independent PDK1 subfamily. Consisting of 23 kinases, the AGCVIII subfamily forms the plant specific major subfamily within the AGC family. Adapted from Bögre et al. (2003).

Dittrich and Devarenne 2012). Reduced PDK1 activity leads to severe developmental defects in animal organisms (Mora et al. 2004), and knockout of *PDK1* causes embryo-lethality in mice (Lawlor et al. 2002), and double knockdown of both *PDK1* genes in *Solanum lycopersicum* (tomato) is lethal as well (Devarenne et al. 2006). *Physcomitrella patens* *PDK1* knockout elicits strongly impaired growth and severely decreased resistance to abiotic stress (Dittrich and Devarenne 2012). Moreover, *ospdk1* mutants in rice (*Oryza sativa*) display a moderate dwarf phenotype (half-size of WT), and overexpression leads to increased disease resistance (Matsui et al. 2010).

INTRODUCTION

Interestingly, Arabidopsis double knockout plants (*pdk1.1 pdk1.2*) depict only very mild phenotypes regarding plant height and silique length but are strongly impaired in *Piriformospora indica*-induced growth promotion (Camehl et al. 2011). As mentioned above, PDK1 acts as the master kinase of AGC kinase signaling in mammals. The two Arabidopsis PDK1s were shown to activate various AGC kinases through the phosphorylation of the T-loop of the substrates (Bögre et al. 2003, Anthony et al. 2004, Zegzouti et al. 2006a, Zegzouti et al. 2006b) but for the others the upstream regulators remain unknown. Several AGC kinases comprise a short PDK1-interacting fragment (PIF motif, FxxF) at their C-terminus, which is thought to be responsible for the interaction between PDK1 and its target kinases. In addition, another highly conserved motif (Ade) was identified (Kannan et al. 2007), and shown to mediate interaction between PDK1 and AGC kinases (Romano et al. 2009), which is highly conserved among animal AGC kinases but not present in AGCVIII kinases of plants (Zhang and McCormick 2009). In vitro studies suggest that plant PDK1s interact in a quite promiscuous fashion with AGCVIII kinases, which leads to a significant increase of auto- and transphosphorylation of several AGCVIII kinases (Anthony et al. 2006, Devarenne et al. 2006, Zegzouti et al. 2006a, Zegzouti et al. 2006b). PDK1 phosphorylates a conserved threonine residue within the T-loop of animal AGC kinases (Romanelli et al. 2002). AGCVIII kinases possess a conserved serine residue at the same position, which represents a phosphorylation target of PDK1 (Anthony et al. 2004, Devarenne et al. 2006, Zegzouti et al. 2006a). These observations suggest an evolutionary conserved PDK1-mediated mechanism of AGC kinase regulation. Despite the in vitro phosphorylation characteristics, it remains unknown if PDK1 is the master regulator of AGCVIII kinase for various reasons. First, the activity of many AGCVIII kinases is increased by PDK1 in vitro but does not depend on the presence of PDK1 (Anthony et al. 2004, Devarenne et al. 2006, Zegzouti et al. 2006a). The second point is that neither spatiotemporal expression patterns by in situ hybridization or promoter-reporter constructs nor localization studies of PDK1 have been carried out so far. Additionally, the absence of a severe *pdk1.1 pdk1.2* developmental phenotype in Arabidopsis makes it difficult to debate about PDK1's role as a master regulator of AGCVIII kinases. It was speculated that there might be a third kinase with overlapping PDK1 functions, which shares only little sequence similarity with PDK1, and has therefore not been identified yet (Zhang and McCormick 2009, Zulawski et al. 2014). Other upstream regulators of AGCVIII kinases have become subjects of the discussion, such as the secondary messengers Ca²⁺, cAMP, cGMP, and phospholipids (Zhang and McCormick 2009). Benjamins et al. (2001) showed that PID BINDING PROTEIN 1 (PBP1) and TOUCH3 contain EF-hands and interact with PID in a Ca²⁺-dependent manner. Ca²⁺ and a calmodulin inhibitor repress PID activity (Benjamins et al. 2003, Zegzouti et al.

2006a). Although AGCVIII kinases do not contain recognizable lipid binding domains (van Leeuwen et al. 2004), PID was shown to bind several phospholipids in vitro (Zegzouti et al. 2006b). Furthermore, OXI1 activity increases upon phosphatidic acid treatment in a PDK1-dependent manner (Anthony et al. 2006). Besides others, these findings open a new sight on PDK1-dependent and -independent AGCVIII kinase regulation.

1.2.3 UNICORN – a suppressor of ectopic growth

Figure 1-5 Confocal micrographs of mPS-PI stained ovules depicting protrusion formation.

(A) *Ler* WT, and (B – F) several ovule mutants are shown. Please note protrusion formation in dominant *sk21-D* line (C and D); and enhanced phenotype in *ucn-1 sk21-D* double mutants (E) strongly enlarged and (F) multiple protrusions (compare with B and D). Arrows indicate protrusions. Scale bars: 20 μ m. Figure from Enugutti and Schneitz (2013).

Originally described by Schneitz et al. (1997), *ucn* mutants show aberrant cell divisions and ectopic growth in ovule integuments (Figure 1 3), stamens, petals and cotyledons but never on sepals or carpels (Enugutti et al. 2012). The earliest ectopic outgrowths were observed in stages 2-IV/V but usually the protrusions become obvious in later developmental stages (from early stage 3). Cells of the abaxial inner or the adaxial outer integument dividing periclinally and/or obliquely instead of strictly anticlinally cause the initiation of the outgrowth. These aberrant divisions lead to the introduction of additional cell layers, which will be surrounded by the outer layers, i.e. the two layers of the outer integument or only the outermost abaxial layer (Enugutti et al. 2012). In *ino-2 ucn-1* double mutants, it was shown that the presence of an outer integument is not necessary for the formation of aberrant divisions in the inner integument. The authors showed that the cells contributing to the outgrowth exhibit at least partial integument identity rather than callus (Enugutti et al. 2012). The *UCN* gene encodes an active AGCVIII kinase that facilitates ectopic growth suppression in integuments by directly repressing the KANADI TF ATS

INTRODUCTION

(Enugutti et al. 2012). Overexpression of *ATS* within its own expression domain in the dominant activation tagging line *sk21-D* (Gao et al. 2010) causes *ucn*-related protrusion arising from the integuments, and in *ucn-1 sk21-D* lines the protrusion are strongly enlarged (Figure 1-5). This suggests a model, in which the levels of active UCN and *ATS* relative to each other are of critical relevance in the process of ectopic growth suppression in integuments (Enugutti and Schneitz 2013).

Figure 1-6 Floral phenotypes of *ap3 ucn*, *ag ucn* and *ap2 ucn* double mutants.

Light micrographs of (A) *Ler* WT, (B) *ucn-1*, (C) *ap3-3*, (D) *ap3-3 ucn-1* (please note absence of protrusions on sepals), (E) *ag-1*, (F) *ag-1 ucn-1* (please note presence of petal protrusions in second- and third-whorl

(arrows)), (G) *ap2-8*, and (H) *ap2-8 ucn-1* (please note protrusions on first-whorl ovules (arrow)). Scale bars: 0.5 mm. Figure from Enugutti and Schneitz (2013).

Several double mutants between *ucn-1* and floral homeotic mutants (Figure 1-6) such as *ucn-1 agamous-1 (ag-1)*, *ucn-1 apetala2-8 (ap2-8)* and *ucn-1 apetala3-3 (ap3-3)* displayed that *UCN* acts in an organ- and not in a whorl-specific fashion (Enugutti and Schneitz 2013). Furthermore, the authors showed that *ucn-1* protrusions arise in an auxin- and cytokinin-independent manner, and that *UCN* acts autonomously with respect to *ETT* and *ARF4* (Enugutti and Schneitz 2013) suggesting that *UCN* is independent of the *ATS/ETT* protein complex important for integument initiation. Upstream regulators and downstream targets of *UCN*, besides *ATS*, remain unknown. *UCN*'s nature as an AGCVIII kinase raises the question whether *PDK1* is involved in the regulation of *UCN* signaling during floral organ and ovule development.

Figure 1-7 *ucn ett* and *ucn ett arf4* ovules depict additive phenotypes.

Scanning electron micrographs of (A, B, D, E, G, H) stage 4 ovules, and of (C, F) flower stage 14 gynoecia. (A) *Ler* WT, (B) *ucn-1*, (C) *ett-1* gynoecium, (D) *ett-1* ovule, (E) *ucn-1 ett-1* ovule, (F) *ett-1 arf4-1* gynoecium, (G) *ett-1 arf4-1* ovule, and (H) *ucn-1 ett-1 arf4-1* ovule. Please note the additive phenotypes in E and H (compare with B, D and B, G. Arrows indicate protrusions. Scale bars: 20 μ m. Figure from Enugutti and Schneitz (2013).

1.3 Tumorigenesis in animals and plants

Commonly, a tumor is defined as a neoplastic outgrowth, in which the tumorous cells are not in coordination with the surrounding ‘normal’ cells anymore caused by ectopic cell proliferation. This definition pertains for animals (Weinberg 2014) as well as for plants (Doonan and Sablowski 2010). Animal tumors can be subdivided into benign and malignant tumors. Benign tumors, such as lipomas or adenomas for instance, are neoplasms spatially restricted in growth that usually grow slowly, display distinct boundaries, and contain differentiated cells. They are non-invasive and do not develop metastases. By contrast, malignant tumors (cancers), for example testicular or mammary carcinoma, consist of diversely or poorly differentiated cells combined with high levels of genomic instability, grow invasively and uncontrollably, and develop metastases at a certain point of time (Weinberg 2014). Based on this definition, all observed plant tumors so far are of benign origin (Ahuja 1965, Braun 1972, Braun 1975, Dodueva et al. 2007, Doonan and Sablowski 2010). The absence of metastatic spread like in animal cancers is explained by the presence of rigid cell walls that surround and fix plant cells (Doonan and Sablowski 2010).

In animals, many tumor suppressor genes have been identified in the last decades of cancer research. Amongst many others, AGC kinase family members playing pivotal roles in the regulation of proliferation and expansion were shown to be involved in tumorigenesis and cancerogenesis (Pearce et al. 2010). For instance, the AGC kinase Warts/LATS that represents a core component of Hippo signaling necessary for tumor suppression and organ size regulation (Halder and Johnson

2011). Mutations in *Warts/LATS* lead to tumorigenesis in mouse and *Drosophila* (Justice et al. 1995, Xu et al. 1995, St John et al. 1999). As well as loss-of-function, increased activity of AGC kinases such as Akt/PKB have been demonstrated to be involved in cancer in humans (Vivanco and Sawyers 2002, Carpten et al. 2007). Beyond that, the central regulator of animal AGC kinases, PDK1, is associated with a variety of human cancers such as melanomas, breast, prostate, and gastric cancer (Gagliardi et al. 2017). For detailed information on the role of PDK1 in human cancer, see section 1.3.4.

1.3.1 Pathogen-induced tumors

Most tumor formation in plants is caused by a variety of pathogens, i.e. bacteria, fungi or viruses. Several bacteria were shown to cause ectopic outgrowth on their respective host plants including the genus *Agrobacterium* (Lippincott and Lippincott 1975, Gelvin 2003), *Pantoea agglomerata* pv. *gypsophilae* (Chalupowicz et al. 2006), *Pseudomonas savastanoi* (Wilson and Magie 1964, Wilson 1965, Glickmann et al. 1998, Temsah et al. 2010), and *Rhodococcus fascians* (Vandeputte et al. 2005). These bacteria lead to the formation of gall tumors with variable sizes. In order to implement the tumor-inducing molecular mechanisms, all tumor-inducing bacteria have achieved the ability, which is determinate on either their plasmids (e.g. Ti-plasmids of *Agrobacterium tumefaciens*) or their chromosomal genes (Morris 1986), to control cytokinin and auxin synthesis in the host plant. The best-studied tumor-inducing bacterium is *A. tumefaciens* due to its utilization in the generation of genetically modified plants (Bechtold et al. 1993, Clough and Bent 1998).

Few plant viruses are also capable of tumor induction. The *Geminiviridae* family (Nagar et al. 1995), and *Phytoreoviruses* of the *Reoviridae* family (Streissle and Maramorosch 1963, Kudo et al. 1991) represent two examples of tumor-inducing plant viruses. *Geminiviruses* interfere directly with the central cell cycle control machinery (Hanley-Bowdoin et al. 2004, Desvoyes et al. 2006, Ascencio-Ibáñez et al. 2008, Doonan and Sablowski 2010), which is interesting regarding the fact that aberrant activity of central cell cycle control genes does not cause tumor formation in plants (Beemster et al. 2003, Doonan and Sablowski 2010, Harashima and Schnittger 2010).

In addition, some fungi have the ability to cause tumor formation on their host plants. For example *Ustilago maydis* induces tumors on maize plants by fungal protein transfer to (Brefort et al. 2009, Skibbe et al. 2010), and induction of auxin synthesis and expression of auxin-responsive

genes in the host cells (Doehlemann et al. 2008). Other examples for tumor-inducing fungi are *Taphrina deformans* that leads to tumor formation on peach leaves by increasing cytokinin and auxin levels (Sziraki et al. 1975, Tavares et al. 2004), an *Dibotryon morbosum* (*Apiosporina morbosa*), which causes black knot galls on plants of the *Rosaceae* family (Fernando et al. 2005).

Furthermore, plant tumors can be induced by root-knot nematodes, cyst nematodes (Bird and Koltai 2000, De Meutter et al. 2003), protists such as *Plasmodiophora brassicae* (Devos et al. 2005), and several insects such as gall wasps, aphids and flies (Armstrong 1995).

1.3.2 Genetic tumors

Genetic alterations can cause spontaneous tumor development without presence of exogenous agents or pathogens. Knowledge gained in animal tumor formation, suggests that genetic lesions in genes of core cell cycle regulation result in overproliferation and tumorigenesis in plants as well. Various plant tumors caused by several agents exhibit aberrant behavior of genes involved in different steps of cell cycle control (Frank et al. 2002, Harrar et al. 2003, Lee et al. 2004). Interestingly, alterations in many core cell cycle genes does not lead to neoplasm development (Beemster et al. 2003, Doonan and Sablowski 2010, Harashima and Schnittger 2010). For instance, null-alleles of *RETINOBLASTOMA-RELATED* (*RBR*), the single Arabidopsis ortholog of the outstanding human tumor suppressor *Rb*, do not cause tumor formation (Ebel et al. 2004, Wachsmann et al. 2011). In contrast to animals, plants seem to be quite resistive to tumor formation but some genetic examples for tumorigenesis in plants are known, which involve complex genetics. Spontaneous genetic tumors appear in interspecies hybrids in particular (Ahuja 1998). Although some examples including tumor formation in tobacco flowers (Kostoff 1939, Sharp and Gunckel 1969), *Datura* ovules (Blakeslee and Satina 1947), and tomato leaves (Martin 1966) have been demonstrated quite long time ago, the underlying genetic mechanisms remain mostly unknown.

Single-locus lesions can cause the formation of tumorous structures in plants (Nuttall and Lyall 1964). In the last decades, progress on the identification of single-loci has been made, and a few examples are presented here. Dominant neomorphic alleles of the maize homeobox gene *Knotted-1* (*Kn-1*) lead to ectopic *Kn-1* expression resulting in leaf 'knots' (Freeling and Hake 1985, Smith et al. 1992), and over-dominant allele compilations of the *OUTGROWTH-ASSOCIATED KINASE* (*OAK*) locus cause ectopic outgrowth on Arabidopsis leaf petioles (Smith et al. 2011). Moreover, very-long-chain fatty acids (VLCFAs) were shown to play a critical role in plant growth

through the investigation of the pleiotropic *gurke (gk)/pepino (pep)/pasticcino (pas)* mutants. These mutants show ectopic cell proliferation, and the respective genes are involved in VLCFA biosynthesis (Torres-Ruiz et al. 1996, Faure et al. 1998, Haberer et al. 2002, Baud et al. 2004, Roudier et al. 2010). Furthermore, mutants of the genes *TUMOROUS SHOOT DEVELOPMENT1/KORRIGAN (TSD1/KOR)* and *TSD2/QUASIMODO2 (QUA2)*, which are involved in pectin and cellulose biosynthesis, show callus formation at the apex (Frank et al. 2002). These findings suggest a crucial role of the cell wall in the control of cellular growth (Mouille et al. 2007, Krupková et al. 2007, Krupková and Schmülling 2009). The maintenance of abaxial-adaxial polarity in lateral organs is of crucial importance to restrict growth (Eshed et al. 2001, Eshed et al. 2004, Pekker et al. 2005, Nakata and Okada 2013). The above-described *ett arf4* double mutant as well as the *kan1 kan2* double mutant show aberrant abaxial outgrowth on leaves (Eshed et al. 2001, Pekker et al. 2005), proposing an important role in abaxial fate determination for the auxin response factor family members ETT and ARF4 (Ulmasov et al. 1999, Remington et al. 2004).

Recently, the above-described AGCVIII kinase UCN was shown to act as an Arabidopsis tumor suppressor gene in ovules by repressing the KANADI TF ATS (Enugutti et al. 2012, Enugutti and Schneitz 2013). Other components of UCN-mediated control of division plane orientation and planar growth remain unexposed.

1.3.3 (Phyto-) hormones in tumorigenesis

Hormones in animals as well as phytohormones in plants play pivotal roles in growth regulation, development and tumorigenesis. For example, altered estrogen and progestogen levels are related to the development of breast cancer as they act with and through proto-oncogenes and growth factors to alter normal breast cell proliferation (MacMahon et al. 1973, Pike et al. 1993), and hypothalamic hormones are involved in the malignant growth formation in many different human organs, e.g. prostatic, ovarian, breast, and pancreatic cancers (Schally et al. 2001). In plants, altered cytokinin and auxin homeostasis occasionally relate to dedifferentiation and tumor formation (Sziraki et al. 1975, Morris 1986, Ahuja 1998, Tavares et al. 2004, Dodueva et al. 2007, Doonan and Sablowski 2010). In addition, phytohormones control various cell cycle regulators. For example, some cyclins and cyclin-dependent kinases were found to be upregulated in response to auxin or cytokinin (Chung and Parish 1995, Riou-Khamlichi et al. 1999, Roudier et al. 2003, Sieberer et al. 2003). Taken together, animal and plant hormones have the ability to

induce or enhance tumor formation and growth by interfering with the cell cycle control machinery.

1.3.4 AGC kinases in tumorigenesis

As described above, several animal AGC kinases, such as Warts/LATS (Justice et al. 1995, Xu et al. 1995, St John et al. 1999, Halder and Johnson 2011) and Akt/PKB (Vivanco and Sawyers 2002, Carpten et al. 2007) have been described to be involved in tumorigenesis. Among the human AGC kinases, one of them plays the central role in tumor formation and proliferation in various tissues: PDK1. This so-called master regulator of AGC kinase signaling is overexpressed in many different tumors (Gagliardi et al. 2017). Most forms of mammary carcinoma show *PDK1* overexpression caused by increased copy number, which is often associated with other genetic alterations in *Akt* signaling (Maurer et al. 2009). In castration-resistant prostate cancer and lymph node metastases, the *PDK1* containing locus is frequently amplified (Choucair et al. 2012), and in esophageal squamous cell carcinoma cells more PDK1 is abundant compared to non-cancerous adjacent cells and higher levels of PDK1 are associated with increased severity of this cancer type and poor prognosis (Yang et al. 2014). Furthermore, *PDK1* overexpression is related to melanoma (Scortegagna et al. 2014), acute myeloid leukemia (Zabkiewicz et al. 2014), hepatocellular carcinoma (Wang et al. 2016), and to gastric cancer, in which the level of PDK1 abundance negatively correlates with survival rates (Bai et al. 2016). In plants, PDK1 has not yet been associated with tumor formation. In general, only UCN as an AGC kinase within the plant kingdom was shown to be involved in tumorous outgrowth suppression in a phytohormone-independent manner so far (Enugutti et al. 2012).

1.4 Objectives

3-Phosphoinositide-dependent protein kinases (PDK1s) play pivotal roles in all eukaryotic kingdoms of life. In humans, *PDK1* is crucial in many developmental and physiological processes including tumorigenesis and cancer. In contrast to mammals, the functions of plant PDK1 proteins are poorly understood. In this study, I wanted to examine the role of the two *Arabidopsis PDK1* genes in general and their specific roles with respect to the UCN signaling pathway in the control of planar growth.

In addition, I was interested to elucidate the relationship between ATS, which was shown to be a component of *UCN* signaling in integuments, and PDK1.

My data imply that PDK1 is able to activate UCN and that the activated UCN directly represses PDK1 in order to maintain the cell division planes in petals and ovules in an anticlinal orientation. Both, PDK1 and ATS need to be present for protrusion formation in *ucn-1* ovules.

2 MATERIAL AND METHODS

2.1 Plant work, Plant Genetics and Plant Transformation

Arabidopsis thaliana (L.) Heynh. var. Columbia (Col-0) and var. Landsberg (*erecta* mutant) (*Ler*) were used as wild type strains. Plants were grown as described earlier (Fulton et al. 2009). The *ucn-1* mutant (in *Ler*) was described previously (Enugutti et al. 2012), and *pdk-1* T-DNA lines were described before (Camehl et al. 2011). T-DNA insertion lines were received from the NASC (*pdk1.1-1* SALK_053385, *pdk1.1-2* SALK_113251, *pdk1.2-2* SAIL_62_G04, *pdk1.2-3* SAIL_450_B01). Wild type *Ler* and Col-0 and *pdk1.1 pdk1.2* mutant plants were transformed with different constructs using *Agrobacterium* strain GV3101/pMP90 (Deak et al. 1986, Sambrook et al. 1989) and the floral dip method (Clough and Bent 1998). Transgenic T1 plants were selected on Hygromycin (25 µg/ml) plates, and around 10 dag, viable seedlings were transferred to soil for further inspection.

2.2 Recombinant DNA work

For DNA and RNA work standard molecular biology techniques were used. PCR-fragments used for cloning were obtained using Phusion or Q5 high-fidelity DNA polymerase (both New England Biolabs, Frankfurt, Germany). All PCR-based constructs were sequenced (Eurofins Genomics, Ebersberg, Germany). The Gateway-based (Invitrogen) pDONR207 was used as entry vector, and destination vectors pMDC43 and pMDC83 (Curtis and Grossniklaus 2003) were used as binary vectors. Detailed information for all oligonucleotides used in this study is given in table 7-1 in the supplement.

A PCR standard protocol:

1. 95 – 98°C → 5 min
2. 95 – 98°C → 20 s
3. 55 – 60°C → 20 s
4. 72°C → (Phusion and Q5 polymerase 30 s/kb; Taq 60 s/kb)
5. 72°C → 5 min
6. 16°C → pause. Steps 2 – 4 were repeated for 30 – 38 cycles.

2.3 Quantitative real-time PCR

Tissue for quantitative real-time PCR was harvested from 30-day old plants grown under long day conditions. Tissue was harvested into Eppendorf tubes, snap frozen in liquid nitrogen, and stored at -80°C. With minor changes, RNA extraction, DNase treatment using rDNase (Macherey-Nagel, Düren, Germany) and quality control were performed according to the manufacturer's instruction (Macherey-Nagel, Düren, Germany). First-strand cDNA was synthesized from 0.5 - 1.0 µg of total RNA via reverse transcription, using the First Strand cDNA Synthesis Kit (ThermoFisher, Schwerte, Germany). Quantitative real-time PCR was performed in the 2 step + MeltCurve programme on a CFX 96 Touch™ Real-Time PCR detection system (Bio-Rad Laboratories GmbH, Munich, Germany) using the GoTaq Real-Time qPCR kit (Promega, Mannheim, Germany), and analysis was done essentially as described (Enugutti et al. 2012). Using the $\Delta\Delta$ -Ct method, *PDK1.1* and *PDK1.2* gene expression levels were normalized against At4g33380, At2g28390, and At5g46630 expression. Primer pairs are given in table S1.

2.4 Reporter Constructs

For plasmid pPDK1.2::gPDK1.2:EGFP pMDC83, 4.253 kb of *gPDK1.2* sequence was amplified from Col-0 genomic DNA including promoter sequence spanning genomic DNA up to the 3' end of the adjacent gene (1.245 kb) and 3'UTR of *PDK1.2* and cloned into pDONR207. pMDC83 (35S promoter was removed) was used as destination vector. For overexpression constructs, *gPDK1.1* or *gPDK1.2* were amplified from Col-0 genomic DNA and cloned into pDONR207. As destination vectors, pMDC43 or pMDC83 (35S promoter was replaced by either pUBQ10 or p16) were used, respectively. Reporter constructs were cloned by lab technician Regina Hüttl.

2.5 CRISPR/Cas9 Constructs

Therefore, I made use of the system developed by Wang et al. (2015), in which an egg cell specific promoter (*pEC1.2*) controls *Cas9* expression. I designed a single guide RNA (sgRNA) binding to the region +346 to +365 of the *UCN* coding sequence. The destination vector pHEE401 containing this sgRNA under control of the *U6-26* promoter and the plant optimized *Cas9* coding sequence under control of *pEC1.2* was transformed into *Ler* and Col-0 WT plants. I thank Qi-Jun

Chen (China Agricultural University, Beijing) and Stefanie Sprunck (University of Regensburg, Germany) for providing the CRISPR plasmid pHEE401 and pCBC-DT1T2.

2.6 Generation, Expression and Purification of Recombinant Proteins

UCN and PDK1 coding sequences were amplified from floral cDNA (*Ler*) and cloned into pGEX-6P-1 (UCN versions; GE Healthcare, Munich, Germany), pMal-c2x (PDK1 versions; New England Biolabs, Frankfurt, Germany), or pET32a (ATS; Novagen, now Merck, Darmstadt, Germany). The clones were expressed in the *E. coli* strain BL21 (DE3) pLysS. Expression from the pGEX vector leads to proteins fused to a N-terminal Glutathione Transferase (GST) protein, expression from pMal leads to proteins fused to a N-terminal Maltose Binding Protein (MBP). For protein expression and purification, bacterial cultures were grown to OD 0.6-0.8 at 37°C. Then, the bacteria were induced with 0.8 mM isopropyl-beta-thio galactopyranoside (IPTG) for UCN and 1.5 mM IPTG for PDK1 and grown at 30°C for 4 h. Subsequently, the recombinant proteins were purified from the bacteria by batch purification under native conditions using the Glutathione Sepharose 4 Fast Flow (GE Healthcare) for GST fusion proteins and Amylose resin (New England Biolabs) for MBP fusion proteins according to the manufacturer's instructions. As elution buffers 1xPBS supplemented with 10 mM reduced glutathione or 10 mM maltose was used, respectively. For PDK1, four different protein versions were expressed and purified (PDK1.1 WT, PDK1.1_{KD} (kinase deficient version containing a K73A mutation), PDK1.2 WT and PDK1.2_{KD} (kinase deficient version containing a K74A mutation)). For UCN, five different protein versions were expressed and purified (UCN WT, UCN_{G165S} (*ucn-1* mutation, kinase deficient), UCN_{KD} (kinase deficient version containing a K55E mutation), UCN_{ΔPIF} (kinase active version lacking the PIF motif at the C-terminus), and UCN_{KD/ΔPIF} (kinase deficient version lacking the PIF motif at the C-terminus)). For ATS, WT versions and single, double and triple mutants for S13A, S92A, and S211A were used. For MST measurements, the purified proteins were labeled with NT-647 and subsequent MST measurements were performed according to the manufacturer's instructions (NanoTemper GmbH, Munich, Germany).

2.7 In vitro kinase assay

For kinase assays, the proteins were purified as described above and concentrations were estimated on a 12% SDS PAGE using BSA as standard protein. Assays were performed with approximately 500 ng of respective protein(s) and incubated in HMK buffer (10 mM HEPES, 10 mM MgCl₂, 10 μM ATP and 2 μCi of either γ-³²P-ATP or γ-³³P-ATP (Hartmann Analytik, Braunschweig, Germany)) at RT for 1 h. Reactions were stopped by adding 4 μL 6xLaemmli buffer and boiling at 95°C for 5 min. In order to separate the proteins, 12% SDS PAGE was performed. Subsequently, the gels were stained with Coomassie Brilliant Blue G250, destained in 10% acetic acid and dried. Phosphorimager plates were exposed at RT over night and signals were detected using a Fuji BAS Phosphorimager (Fujifilm, Düsseldorf, Germany).

2.8 Yeast Two-Hybrid assay

For yeast two-hybrid assays, the above-mentioned four PDK1 and five UCN versions were used. The coding sequences of these versions were cloned into pGBKT7 and pGADT7 vectors, respectively (Clontech Laboratories/Takara Bio, Saint-Germain-en-Laye, France). Plasmids were transformed into yeast strain AH109 and transformants were selected on SD_{-LW} medium (SD medium without Leu and Trp). Three independent colonies of each combination were resuspended each in 500 μL ddH₂O, diluted 1:100 and 10 μL of the dilutions were spotted on SD_{-LWHA} (SD medium without Leu, Trp, His and Adenine) supplemented with 5 mM 3-AT and grown at 30°C for 3 days.

2.9 BiFC assay

For Bimolecular Fluorescence Complementation (BiFC), the above-mentioned four PDK1 and five UCN versions were cloned into pSPYCE-35S and pSPYNE-35S vectors, respectively (Walter et al. 2004). Plasmids were transformed into Col-0 mesophyll protoplasts as published (Yoo et al. 2007). Protoplasts were incubated gently shaking at 21°C in the dark for 10 – 15 h and subsequently imaged using a FV1000 confocal microscope (Olympus, Hamburg, Germany) with excitation at 515 nm and detection at 521 – 559 nm for YFP fluorescence. At least 800 viable protoplasts per combination were analyzed using a FV1000 confocal microscope.

2.10 In Situ Hybridization and Microscopy

Whole mount in situ hybridization of ovules was performed according to Bleckmann and Dresselhaus (2016). Digoxigenin-labeled probe generation has been described earlier (Sieber et al. 2004). For microscopic analysis of in situ hybridizations, an Olympus BX61 upright microscope with DIC optics was used. Whole mount in situ hybridization was performed by lab technician Katrin Wassmer.

Confocal laser scanning microscopy using modified pseudo-Schiff propidium iodide (mPS-PI) staining or detection of EGFP was performed as described earlier (Vaddepalli et al. 2014). mPS-PI staining was performed according to Truernit et al. (2008). Whole flowers and silique micrographs were obtained using an Olympus SZX12 stereomicroscope equipped with a XC CCD camera and Cell Sense Dimension software.

2.11 Growth media, growth conditions and frequently used buffers

Ingredients are dissolved in deionized H₂O, and all media need to be autoclaved.

Lysogeny broth (LB) medium (for standard molecular biology/cloning):

1% tryptone, 0.5% yeast extract, 10% NaCl, (0.9% bacto agar)

Terrific broth (TB) medium (for protein expression in *E.coli*):

1.2% tryptone, 2.4% yeast extract, 0.5% glycerol

Dissolve in deionized water and autoclave. Add 1/10 of the final volume of 10x TB phosphate buffer (0.17 M KH₂PO₄, 0.72 M K₂HPO₄).

½ Murashige-Skoog medium (for plant tissue culture):

0.22% MS medium powder, (1% sucrose), 0.9% Agar (plant cell culture tested)

YPD medium (yeast rich medium):

2% tryptone, 1% yeast extract, (2.4% bacto agar), 2% glucose

MATERIAL AND METHODS

SD-LW:

0.67% yeast nitrogen base (double drop-out; SD lacking leucine and tryptophan), 2% glucose, (2% bacto agar)

SD-LWH:

0.67% yeast nitrogen base (triple drop-out; SD lacking leucine, tryptophan and histidine), 2% glucose, (2% bacto agar)

SD media might be supplemented with 5 – 10 mM 3-AT.

YEB medium (*A. tumefaciens* liquid culture for plant transformation):

0.5% beef extract, 0.1 % yeast extract, 0.5% tryptone, 0.5% sucrose, 0.5 g/L MgCl₂

SOC medium (for regeneration of *E.coli* after transformation):

0.5% yeast extract, 2% tryptone, 10 mM NaCl, 2.5 mM KCl, 20 mM glucose, supplemented with 20 mM Mg²⁺ (10 mM MgCl₂; 10 mM MgSO₄) after autoclaving.

10x PBS:

30 mM NaH₂PO₄, 70 mM Na₂HPO₄, 1.3 M NaCl

5x TBE:

450 mM Tris Base, 400 mM boric acid, 10 mM EDTA pH 8, pH should be 8.3

Growth conditions were as follows: *E.coli* for standard molecular biology was grown at 37°C over night. *E.coli* BL21(DE3) for protein expression and purification was grown at 37°C until they reached OD₆₀₀ = 0.5 – 0.6. Subsequently, IPTG was added to a final concentration of 0.8 mM (for GST-UCN version), 1.5 mM (for MBP-PDK1 versions) and 1 mM (for Trx-6xHis-ATS) and the cells were incubated at 30°C for another 4 h. Yeast AH109 was grown at 30°C for 2 – 3 d. Seedlings were grown on ½ MS with or without 1% sucrose at 22°C and continuous light for 8 – 12 d.

MATERIAL AND METHODS

Antibiotics for bacterial selection were used at final concentrations as follows: Kanamycin 50 µg/mL; Ampicillin 100 µg/mL; Spectinomycin 100 µg/mL; Gentamycin 25 µg/mL; Tetracyclin 12.5 µg/mL; and Rifampicin 10 µg/mL.

2.12 Bioinformatics

Bioinformatic analysis was mainly performed using geneious software. Alignments were generated with geneious software using a ClustalW algorithm with BLOSUM62 matrix. Sequencing results were analyzed in geneious software using the map to reference tool with geneious mapper and highest sensitivity.

3 RESULTS

3.1 Characterization of the Arabidopsis AGC kinases PDK1.1 and PDK1.2

3.1.1 Structure-function properties of PDK1 and conservation between the two Arabidopsis PDK1 and PDK1 proteins of other plant species

In order to evaluate the importance of 3-phosphoinositide-dependent protein kinases (PDK1), I have performed *in silico* analyses regarding structural and functional properties and conservation within the plant kingdom. PDK1 shows unique structural and functional properties within the AGC kinase family. This kinase is the only plant AGC kinase containing a lipid-binding domain, the Pleckstrin Homology (PH) domain. This domain facilitates the interaction of PDK1 with phospholipids such as phosphatidic acid in order to transduce signals from outside the cell usually via other AGC kinases to adapt the expression patterns and/or levels of target genes or modify enzymatic activity in order to respond to intrinsic or environmental changes. Besides the presence of the PH domain and the PIF binding pocket, which enables PDK1 to interact with downstream AGC kinases containing a PDK1 interacting fragment (PIF), the structural properties resemble standard kinase structure including an activation segment starting with the Magnesium-binding loop DFG and containing a conserved T-residue in the so-called T-loop.

Figure 3-1 Schematic depiction of PDK1 domain structure.

The Pleckstrin Homology (PH) domain facilitates the interaction with phospholipids such as phosphatidic acid, the T-loop of the activation segment needs to be autophosphorylated to activate the kinase, and the PIF binding pocket ensures the interaction with the substrates of the AGC kinase family.

Since PDK1s are protein kinases of fundamental importance in the life cycle of many eukaryotic organisms, I have analyzed the sequences of 29 flowering plant species using ClustalW algorithm and BLOSUM62 (BLSM62) matrix (-1; for detailed protein sequences see Figure 7-1 in

RESULTS

the supplement). The black bars show highly conserved regions, which are depicted in the identity bar in green (identical) or ocher (highly similar). Here, I found that PDK1 protein sequences of very distinct angiosperm species such as Brassicaceae family members (No. 1 – 10), trees (No. 15, 19, and 23) or important crop plants (No. 26 – 29) show high conservation of more than 75% at the protein sequence level. Excluding *Ricinus communis* and *Vitis vinifera*, the gap of 23 amino acids (AA) at positions 27 to 49 narrows down and results in even higher conservation of the remaining 27 kinases. Two regions, the first one of eleven AA (363 – 373) and the second one of 19 AA at positions 387 – 405 show moderate to little conservation and are therefore variable. Pairwise identity between all 29 analyzed kinases is 82.6 % and pairwise positive are 87 % according to the used BLSM62 matrix. The *in silico* analysis shows high overall conservation of the unique lipid binding AGC kinase among flowering plants leading to the assumption that PDK1 is a kinase of crucial importance as it has been shown for the animal PDK1s (Lawlor et al. 2002, Mora et al. 2004).

Figure 3-2 Alignment of PDK1 protein sequences of different plant species.

Black bars indicate identity or high similarity, grey bars similarity, and light grey bars little similarity. Lines show gaps. Alignment was performed in Geneious software using ClustalW algorithm with BLSM62 matrix. Detailed sequence information is shown in Figure 7-1 in the supplement.

3.1.2 PDK1 expression analysis

In order to examine if the Arabidopsis *PDK1* genes have specific expression properties during plant development or physiological changes in the environment, expression levels of *PDK1.1* and *PDK1.2* were analyzed using AtGenExpress (Kilian et al. 2007). This analysis reveals constant expression throughout plant development with an exception during stamen and pollen development, in which especially *PDK1.2* is strongly upregulated (Figure 3-3). Furthermore, the expression levels of both the *PDK1* genes are quite constant in all applied treatments (light, pathogen, hormone and abiotic stress). Thus, *PDK1* seems not to be specifically involved in particular processes but throughout plant development indicating a role for *PDK1* in many aspects of the Arabidopsis life cycle. In addition to the above mentioned in silico analysis, I performed quantitative Real-Time PCR (qPCR) experiments of stage 9 – 13 flowers, and in situ hybridizations were performed by lab technician Katrin Wassmer (see section 3.2.1.2, Figure 3-9). In these experiments, no significant difference between the two *PDK1* genes as well as the tested tissues could be demonstrated supporting the results from AtGenExpress.

Figure 3-3 Mean-normalized and absolute expression levels of *PDK1.1* (*At5g04510*) and *PDK1.2* (*At3g10540*).

The expression levels of *PDK1.1* (red) and *PDK1.2* (green) according to AtGenExpress (Kilian et al. 2007) are shown. (A) Mean-normalized and (B) absolute expression levels. Both *PDK1*s are expressed in all developmental stages as well as in all other tested conditions (data of light, hormonal, pathogen, and abiotic stress treatments are not shown). Both the *PDK1* genes are expressed at constant levels except for stamen and pollen development, in which especially *PDK1.2* is strongly upregulated.

3.1.3 *pdk1* double knockout plants show a surprisingly mild phenotype

Figure 3-4 Phenotypic characterization of *pdk1* T-DNA lines.

Floral shapes and silique sizes of (A) Col-0 WT, (B) *pdk1.1*, (C) *pdk1.2*, and (D) *pdk1.1 pdk1.2* T-DNA lines are shown. Please note that flowers do not show an obvious phenotype. Siliques of the double insertion lines (DILs) are shorter, slightly thicker and contain less ovules compared to WT and single insertion lines. (E) 35 days old plants of *pdk1.1-1 pdk1.2-2*, *pdk1.1-2 pdk1.2-3* and Col-0 WT (from left to right). DILs exhibit reduced height, single insertion lines (supplemental Figure 7-2) are indistinguishable from WT. (F) Gene structure of *PDK1.1* and *PDK1.2* including T-DNA insertion sites. Grey boxes represent UTRs, black boxes exons, lines introns, and light grey arrowheads indicate primer pairs to determine transcripts in Col-0 and T-DNA lines. Scale bars (flowers) 1mm; (siliques) 2 mm; (E) 10 cm.

In order to examine the phenotypic characteristics of *pdk1* knockout lines, I received two independent T-DNA lines for each of the *PDK1* genes from the Nottingham Arabidopsis Stock Centre (NASC). For *PDK1.1*, I named these lines *pdk1.1-1* (SALK_053385) and *pdk1.1-2* (SALK_113251), and for *PDK1.2* I called them *pdk1.2-2* (SAIL_62_G04) and *pdk1.2-3* (SAIL_450_B01). Insertion sites were analyzed by sequencing. SALK_053385 T-DNA is located 305 bp upstream of the first ATG within the 5' untranslated region (5' UTR), SALK_113251 is integrated within the tenth exon 2255 bp downstream of the first ATG of *PDK1.1*. These lines do not exhibit *PDK1.1* expression by RT-PCR (supplemental Figure 7-2). SAIL_62_G04 was detected within the

RESULTS

fourth exon 858 bp downstream of the first ATG, and SAIL_450_B01 is situated within the sixth intron at position +1311 of the genomic DNA. RT-PCR revealed no transcript in both the *pdk1.2* T-DNA lines (supplemental Figure 7-2). These results corroborate the ones obtained by Camehl et al. (2011), who analyzed two of them before (SALK_113251 and SAIL_450_B01). I have performed subsequent analysis of their phenotypic characteristics in all four above mentioned T-DNA lines and in two independent double insertion lines (*pdk1.1-1 pdk1.2-2* and *pdk1.1-2 pdk1.2-3*, 'DILs'). As shown in Figure 3-4, the single *pdk1* lines do not exhibit any phenotype (A, B) but both DILs differ from the WT slightly in plant height and silique size as well as in number of ovules per silique. Interestingly, the DIL phenotype is not very severe compared to other species, in which a *PDK1* knockout leads often to (embryo) lethality. It was speculated that there might be a third kinase in Arabidopsis with overlapping PDK1 function. Zulawski and colleagues claimed that they found in in silico analyses a third *PDK1* gene, which they named *PDK1.3* (*At2g20050*) (Zulawski et al. 2014). I have analyzed this gene with respect to the two known *PDK1* genes *PDK1.1* (*At5g04510*) and *PDK1.2* (*At3g10540*). In fact, *At2g20050* encodes a PROTEIN PHOSPHATASE 2C (PP2C) containing an additional cyclic nucleotide-binding/kinase domain (Schweighofer et al. 2004, Xue et al. 2008). In my analysis (see supplemental Figure 7-4), I could not reveal any indication that *At2g20050* represents a third Arabidopsis 3-phosphoinositide-dependent kinase 1 (PDK1). The protein encoded by *At2g20050* does neither contain a typical Mg^{2+} -binding site (DFD or DFG) nor a T-loop (CTFVGTAAAY) both crucial for kinase activity. Furthermore, I performed a pairwise alignment using ClustalW algorithm and BLOSUM62 matrix. Whereas the two PDK1 proteins (PDK1.1 and 1.2) exhibit 91.1% identical sites, *At2g20050* shares only 10.4% identity with them (supplemental Figure 7-4). In addition, *At2g20050* comprises a sequence length of 1094 AA whereas PDK1.1 and 1.2 are 491 and 486 AA in length, respectively. Therefore, I strongly doubt that the gene product of the locus *At2g20050* represents a protein with PDK1 function.

3.1.4 Subcellular distribution of PDK1:EGFP fusion proteins

Figure 3-5 Subcellular localization of PDK1.2:EGFP fusion proteins in different tissues.

Confocal micrographs depicting the subcellular distribution of PDK1.2:EGFP fusion proteins under control of the native *PDK1.2* promoter. (A) Anther, (B) cauline leaf, (B') higher magnification of the region in (B), (C) ovule. (D) lateral root, (D') higher magnification of the region in (D), (E) sepal, (E') higher magnification of the region in (E). Arrows indicate the absence of GFP signals at the cell wall, arrowheads indicate plasma membranes, and asterisks indicate absence of GFP signals in the nuclei. Scale bars: 20 μ m.

As shown in section 3.1.2, both *PDK1* genes are expressed throughout all developmental stages in Arabidopsis. In order to investigate the subcellular localization of PDK1, I first explored the SUBA4 database (Hooper et al. 2014, Hooper et al. 2017). Their predictions localize PDK1.1 to

RESULTS

the nucleus and PDK1.2 to the cytosol. Furthermore, I generated *pPDK1.2::PDK1.2::EGFP* lines and analyzed them using a confocal microscope. All lines, native *pPDK1.2::gPDK1.2::EGFP* and overexpressors (under *pUBQ10* or *p16* promoter), show GFP signal distribution within the cytosol (Figure 3-5 and Figure 3-6). I studied all above-mentioned lines in several different tissues and found subcellular distribution to be almost uniform in all lines and tissues. To examine the localization under more natural conditions, I analyzed four lines expressing *pPDK1.2::PDK1.2::EGFP*. These lines showed rescue of the DIL phenotype making it a functional construct. I observed GFP signals in all four lines and all examined tissues. In Figure 3-5 A, the localization of PDK1.2:EGFP in an anther is shown and localization does not differ from those in cauline leafs (Figure 3-5 B and B'), ovules (Figure 3-5 C), and sepals (Figure 3-5 E and E'). In roots (Figure 3-5 D and D'), PDK1.2:EGFP localizes to the cytosol and most likely to the plasma membrane.

Interestingly, PDK1.1:EGFP in overexpressors (driven by *pUBQ10*) also localizes to the cytosol, not in the nucleus as predicted. In roots, I observed that PDK1.1:EGFP is not localizing to nuclei but to the cytosol, the plasma membrane and probably in the endoplasmic reticulum (ER) (Figure 3-6 C and C', arrowheads indicate plasma membranes, asterisks indicate nuclei, and magenta arrows might indicate ER). By contrast, ER localization was not observed in native *pPDK1.2::PDK1.2::EGFP* lines. Taken together, both PDK1:EGFP fusion proteins localize equally to the cytosol in all examined tissues, and the data suggest that PDK1:EGFP localizes as well to the plasma membrane. ER localization might be an artifact of overexpression.

Figure 3-6 Subcellular localization of PDK1:EGFP.

Confocal micrographs depicting subcellular distribution of PDK1:EGFP in overexpression lines. (A) pUBQ10::PDK1.2:EGFP, (B+C) pUBQ10::PDK1.1:EGFP.

(A) Filament, (A') higher magnification of the region in (A), (B) ovule, (C) transition zone of a root, and (C') higher magnification of the region in (C). Arrows in (A') indicate the absence of GFP signal at the cell walls, magenta arrows in (C') indicate most likely endoplasmic reticulum (ER), arrowheads indicate plasma membranes and asterisks indicate nuclei. Scale bars: 20 μ m.

3.2 Mechanism of *UCN*-mediated control of ovule and floral organ development via *PDK1*

PDK1 is known to be a major regulator for AGC kinase signaling in mammals as well as in plants (Pearce et al. 2010). For several AGCVIII kinases of Arabidopsis, *PDK1* is the upstream modulator including *AGC2-1*, which represents one of the closest relatives of *UCN*. Thus, I tested involvement of *PDK1* in *UCN* signaling.

3.2.1 The knockout of either *PDK1* gene almost completely rescues *ucn-1*

The *ucn-1* mutant exhibits aberrant cell divisions and growth aberrations in several tissues, including petals and ovule integuments. These aberrant cell divisions eventually result in tumor-like structures, the so-called protrusions, which consist of differentiated cells (Enugutti et al. 2012). Wild type integument cells divide in a stereotypic anticlinal fashion but *ucn-1* mutants are impaired in these stereotypic divisions. In order to examine whether or not *PDK1* interacts genetically with *UCN*, I analyzed *ucn-1 pdk1* double mutants in homozygous F3 generation. To eliminate effects deriving from the genetic background, I performed three independent crossings of *ucn-1* (female) and Col-0 (male) and reciprocal.

3.2.1.1 Flower and ovule phenotypes

To investigate the role of *PDK1* in *UCN* signaling, I have analyzed a total number of more than 30,000 ovules of three independent crossings of each combination. For each crossing, three independent F3 plants were analyzed (for raw data see Table 7-2 in the supplement). Surprisingly, the knockout of either *PDK1.1* or *PDK1.2* is sufficient to rescue floral and ovule phenotypes of *ucn-1* (Figure 3-7). The *pdk1.1 ucn-1* lines are able to rescue 80 % of the analyzed ovules; *pdk1.2* restores aberrations in 90 % of the ovules of *pdk1.2 ucn-1* double mutants whereas in *ucn-1* Col-0 outcrosses the proportion of intact ovules only increases by 10 % to 20 % ovules without aberrations. Interestingly, the knockout of both *PDK1* genes in *ucn-1* background does not lead to a higher rescue level compared to *pdk1.2 ucn-1* double mutants (Figure 3-7, E).

Here, I show that knockout of only one of the two *PDK1* genes is sufficient to prevent the occurrence of tumor-like outgrowths from the ovule integuments (80 – 90 % rescue), and to restore the floral shape to WT. *pdk1* does not only inhibit the outgrowth of the typical *ucn-1* protrusions but also restores the stereotypic anticlinal division plane within the integuments (Figure 3-7). The result further suggests that *UCN* represses *PDK1* in the control of integument growth and floral organ development.

RESULTS

3.2.1.2 *PDK1* expression is not altered in *ucn-1* mutants

The above-mentioned rescue of *ucn-1* phenotypes by *pdk1* raised the question how *PDK1* is downregulated in the control of planar growth. A previous study indicated that *PDK1.2* transcript levels are increased in inflorescences and stems of *ucn-1* compared to *Ler* (Kirchhelle 2012). In order to exclude that the increment in inflorescences is due to stem contamination, I performed new qPCR experiments together with Annemarie Krauss (internship student) using only flowers without pedicel and stem. Thereby I realized that the forward primer for *PDK1.2* used in Kirchhelle (2012) binds upon a SNP between *Ler* and *Col-0*. It seems that she designed the primers according to *Col-0* sequence, which leads to a mismatch binding in *Ler*. Hence, I designed a new primer according to *Ler* sequence in order to exclude adulteration of transcript levels due to mismatch binding. The results of the new qPCR experiments show that transcript levels are not significantly altered, neither for any *PDK1* nor for the two tested tissues (Figure 3-8). This indicates that *UCN* does not influence the expression levels of the *PDK1* genes.

Figure 3-8 *PDK1.1* and *PDK1.2* expression levels in flowers and stems of *Ler* and *ucn-1*.

Expression is depicted as relative expression normalized against reference genes *At5g25760* (*UBC21*), *At2g28390*, and *At4g33380*. *PDK1.1* expression levels are named '1', and *PDK1.2* expression levels are named '2'. Expression levels are depicted as relative to *Ler* expression (=1). Please note no significant differences between *Ler* and *ucn-1*. p-values (*Ler* vs. *ucn-1*) are as follows: *PDK1.1* flowers p=0.28; *PDK1.1* stem p=0.56; *PDK1.2* flowers p=0.44; *PDK1.2* stem p=0.55. n = 5.

RESULTS

Moreover, I investigated expression patterns of both *PDK1* genes in *ucn-1* mutant ovules compared to *Ler*. Interestingly, the localization of both *PDK1* mRNAs did not show any alterations in *ucn-1* mutants compared to *Ler* WT. Whole mount in situ hybridizations using antisense probe against *PDK1.1* and *PDK1.2* mRNA, respectively, revealed that there was no obvious change in the expression patterns of *PDK1* genes during different stages of ovule development of *ucn-1* and *Ler* are equal. Sense probe controls do not exhibit any signals. Exclusively the nucellus in early developmental stages exhibits no signals (Figure 3-9). Lab technician Katrin Wassmer performed in situ hybridization experiments.

Taken together, the genetic results indicate that *UCN* represses *PDK1*. Enhanced *PDK1* activity is responsible for aberrant cell divisions and abnormal development of ovule integuments and abnormal floral organ shape in *ucn-1* mutants. Thus, the results emphasize the significance of correct negative regulation of *PDK1*.

Figure 3-9 Whole mount in situ hybridizations. Stages of ovule organogenesis (anti-sense, from left to right): 2-V, 3-I to 3-II, and 3-VI; stages according to Schneitz et al. (1995).

Distribution of *PDK1.1* mRNA in (A) *Ler* and (B) *ucn-1* ovules, and distribution of *PDK1.2* mRNA in (C) *Ler* and (D) *ucn-1* ovules of three different developmental stages. The right panel shows sense probe control lacking any signals. Please note that mRNA distribution of both *PDK1s* is equal between

Ler and *ucn-1*, and present throughout ovule development except in nucelli (n) in early developmental stages. Arrows indicate typical *ucn-1* protrusions, in which *PDK1* mRNA is present. Scale bars: 25 μ m.

3.2.2 PDK1 overexpression leads to a *ucn-1*-like phenotype

If *UCN* represses *PDK1* overexpression of *PDK1* in WT should result in a *ucn* phenocopy. In order to test this prediction, I designed several constructs harboring genomic *PDK1.1* or *PDK1.2* (*gPDK1.1/gPDK1.2*) sequence, respectively, under control of either *p16*, *UBQ10* or endogenous *PDK1.2* promoter and fused to *EGFP* (N- or C-terminal). For *pPDK1.2*, I used 1039 bp upstream of *PDK1.2* including 3'UTR of the adjacent gene (AT3G10530). Regina Hüttl (lab technician) cloned

RESULTS

these constructs and I transformed them into WT and into DILs to investigate functionality of the constructs. In comparison to Col-0 WT, plant height and silique length are reduced in *pdk1.1 pdk1.2* double KO lines. Introduction of either *PDK1* gene fused to *EGFP* restores these development restraints to WT levels. As shown in Figure 3-10 (A-C), all constructs restore developmental defects of DILs to WT situation. Furthermore, overexpression leads to a milder *ucn-1*-like floral and ovule phenotypes. I analyzed in total 3056 ovules of five independent lines for each *PDK1*, and compared them with 174 Col-0, 193 *Ler* and 296 *ucn-1* ovules (see Table 3-1). Severity of the observed ovule phenotypes ranges from 6.1% (Line #2-14) to 23.6% (Line #2-1) of ovules show a single protrusion. Additionally, *PDK1* overexpression lines depict polarity defects in root hairs (supplementary Figure 7-3). Root hairs show branching and ballooning. This finding indicates that *PDK1* is involved in cell polarity.

Unlike *ucn-1* mutants, *PDK1_{ox}* lines do not show more than one protrusion in any case, and I did not observe any statistical difference between those lines overexpressing *PDK1.1* and those overexpressing *PDK1.2* (see Figure 3-10 L).

Table 3-1 Ovule phenotypes of *PDK1* overexpressors compared to Col-0, *Ler* and *ucn-1* mutant. Absolute numbers and percentages of respective ovule phenotype are given. #2-1 to #2-14 represent five independent transgenic lines overexpressing *PDK1.2:EGFP*. #1-3 to #1-11 represent five independent transgenic lines overexpressing *PDK1.1:EGFP*.

	#2-1	#2-5	#2-9	#2-11	#2-14	#1-3	#1-4	#1-7	#1-8	#1-11	Col-0	<i>Ler</i>	<i>ucn-1</i>
N	313	282	325	326	296	287	255	328	314	330	174	193	296
no protrusion	239	226	282	265	278	238	214	271	276	291	174	193	27
one protrusion	74	56	43	61	18	49	41	57	38	39	0	0	224
two protrusions	0	0	0	0	0	0	0	0	0	0	0	0	29
>two protrusions	0	0	0	0	0	0	0	0	0	0	0	0	16
% no protr.	76.4	80.1	86.8	81.3	93.9	82.9	83.9	82.6	87.9	88.2	100.0	100.0	9.1
% one protr.	23.6	19.9	13.2	18.7	6.1	17.1	16.1	17.4	12.1	11.8	0.0	0.0	75.7
% two protr.	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	9.8
% >two protr.	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	0.0	5.4

In addition, I determined the expression levels of the above-mentioned ten independent *PDK1:EGFP* overexpression lines. The expression levels correspond to severity of the ovule phenotypes, i.e. the higher the expression level of either *PDK1* the more ovules with neoplastic integument growth I observed (with an exception for lines #2-9 and #2-11, in which #2-9 shows higher expression levels but less outgrowth; compare Table 3-1, Figure 3-10 and Figure 3-11). It

RESULTS

seems that a certain expression level (about 80-fold) causes the strongest phenotype due to overexpression of *PDK1* because even higher levels of *PDK1* transcript do not lead to stronger phenotypes, i.e. in all lines (#2-1, 2-5, 2-9, 1-3, 1-4 and 1-7), in which the expression level reaches 80-fold the proportion of ovules harboring protrusions is around 20%.

Figure 3-11 *PDK1.1* and *PDK1.2* expression in flowers of overexpression lines.

Expression is depicted as relative expression normalized against reference gene *At5g25760* (*UBC21*). (A) *PDK1.1* expression levels relative to *Ler* expression (= 1) in five *PDK1.1* (#1-3 to #1-11) and five *PDK1.2* (#2-1 to #2-14) overexpressors. (B) *PDK1.2* expression levels relative to *Ler* expression (= 1) in five *PDK1.2* and five *PDK1.1* overexpressors. Note log₁₀ scale on the axis of ordinates (y-axis). N = 3 (biological triplicates).

3.2.3 UCN regulates planar growth in ovule integuments and floral organ development through a direct negative regulation of PDK1

The previous results suggest that UCN represses PDK1 in a posttranscriptional manner. To gain more insights into UCN-mediated PDK1 regulation, I designed independent approaches to examine potential direct PDK1-UCN protein-protein interaction. Therefore, I performed *in vitro* kinase, yeast two-hybrid (Y2H) and bimolecular fluorescence complementation (BiFC) assays, and microscale thermophoresis (MST) measurements. These studies show that PDK1 and UCN directly interact. Rescue of *ucn* by *pdk1*, the unaltered *PDK1* expression properties in *ucn-1* mutants and the direct protein-protein interaction between PDK1 and UCN suggest that UCN directly represses protein activity of PDK1.

3.2.3.1 PDK1 and UCN interact in MST assays

Microscale thermophoresis (MST) measurements are based on thermophoresis, also termed Ludwig-Soret effect (Ludwig 1856, Soret 1880). Thermophoresis describes the directed movement of molecules along a temperature gradient, in MST along a microscopic temperature gradient (usually 2 – 4 Kelvin). Thermophoresis depends on the size, charge and solvation entropy of the molecules. The thermophoresis of a fluorescently labeled molecule A differs significantly from the thermophoresis of a complex AB. This difference can be used to determine the binding affinity. The principle of MST was described in detail before (Duhr and Braun 2006, Jerabek-Willemsen et al. 2011).

In order to test whether PDK1 and UCN are able to interact *in vitro*, I employed a MST approach together with Nicole Wenck (Bachelor student). For this purpose, we expressed recombinant proteins in *E. coli* (PDK1 versions N-terminally fused to maltose binding protein (MBP) tags, and UCN N-terminally fused to a glutathione transferase (GST) tag). To measure interactions using MST method, one of the potential interaction partners needs to be fluorescently labeled. Therefore, I labeled MBP, MBP:PDK1.1 and MBP:PDK1.2, respectively, with NT-647-NHS.

To test if MBP can interact with GST *in vitro*, we labeled MBP and used GST as the ligand. This combination does not show any retardation of movement along the 2 K temperature gradient (Figure 3-12C) meaning that MBP and GST do not interact in MST assays. In preliminary MST approaches, *in vitro* interaction between MBP:PDK1.1 or MBP:PDK1.2, respectively, and GST:UCN

RESULTS

was shown (Figure 3-12, A and B). Dose response curves of both combinations (PDK1.1_{labeled} + UCN, and PDK1.2_{labeled} + UCN) display the retardation of movement of the labeled partner (PDK1) with increasing concentrations of the ligand (UCN) along the 2 K temperature gradient.

Nicole Wenck showed in MST experiments, in which she labeled either GST or GST:UCN and used MBP or MBP:PDK1 as the ligand, that these combinations all show retardation of movement with increasing ligand concentrations (not shown). These findings indicate that the GST-tag is – despite the instructions of the manufacturer (NanoTemper, Munich) – not useful for MST measurements, and fluorescently labeling of GST-tagged proteins leads to false positive results.

Figure 3-12 Microscale thermophoresis (MST) measurements of MBP:PDK1_{labeled} and GST:UCN.

Dose response curves of MST measurements are depicted. MBP:PDK1.1, MBP:PDK1.2 or MBP were fluorescently labeled with NT-647, respectively. The labeled protein is held constant, the unlabeled partner (ligand) is applied in a 16 times 1:2 dilution series. (A) Fluorescently labeled MBP:PDK1.1 in combination with GST:UCN. (B) Fluorescently labeled MBP:PDK1.2 in combination with GST:UCN. (C) Control experiment of fluorescently labeled MBP with unlabeled GST. Please note the increase of the normalized fluorescence (F_{norm} [%]) in (A) and (B), whereas F_{norm} is constant in the control (C).

3.2.3.2 PDK1 phosphorylates UCN and vice versa

To better characterize PDK1-UCN interaction in vitro, I performed in vitro kinase assays. In a previous study, in her Master's thesis in our lab, Priya Pimprikar showed interaction between recombinant GST:PDK1 and GST:UCN proteins in kinase assays (Pimprikar 2012). GST is prone to dimerize. To exclude false positive interaction due to GST dimerization, I decided to fuse PDK1 to a maltose-binding protein (MBP) tag and repeat the in vitro kinase assays using recombinant GST:UCN and MBP:PDK1. In order to test if kinase activity and/or the presence/absence of the PDK1-interacting fragment (PIF) influence the in vitro interaction behavior, I heterologously expressed five different UCN versions (namely UCN, UCN_{G165S}, UCN_{KD}, UCN_{ΔPIF}, and UCN_{KD/ΔPIF}), and two different versions of each of the PDK1s (PDK1.1, PDK1.1_{KD}, PDK1.2, and PDK1.2_{KD}) in *E. coli* BL21(DE3)pLysS (see Figure 3-13).

Figure 3-13 Basic structure of UCN and PDK1 proteins.

UCN WT protein consists of 404 AA. The activation segment, which starts with the indicated Mg²⁺-binding loop followed by an insertion domain of 65 AA, the T-loop necessary for kinase activation and ends at the P+1 loop, is flanked by two kinase subdomains. UCN contains a PIF motif (FVDF) at its C-terminus. *ucn-1* mutation results in a G165S substituted version that lacks kinase activity. The UCN_{KD} (kinase deficient) version contains a K55E substitution, in which the conserved lysine residue is replaced by a glutamate. The UCN_{ΔPIF} version is lacking only the last four AA resulting in a protein of 400 AA. In KD/ΔPIF version, the latter two versions are combined. For detailed two-dimensional PDK1 structure, see -1. PDK1_{KD} contains a K73A (PDK1.1) or K74A (PDK1.2) substitution, respectively. Substitution of the conserved lysine residue leads to loss of kinase function.

Figure 3-14 shows that purified MBP:PDK1 fusion proteins are able to trans-phosphorylate all purified GST:UCN_x versions. Autophosphorylation activity of MBP:PDK1.1 and MBP:PDK1.2 is shown in the first lanes, and autophosphorylation of GST:UCN is shown in the second lanes of

RESULTS

Figure 3-14, A and B. GST:UCN lacking the PIF motif (GST:UCN Δ PIF) still shows autophosphorylation activity (Figure 3-14 B, lane 8). No other UCN versions (UCN G_{165S} , UCN KD and UCN KD/Δ PIF) exhibit any kinase activity (A, lanes 8 and 9; B, lane 9). In combination with either MBP:PDK1.1 or MBP:PDK1.2, all GST:UCN $_x$ versions display signals in the autoradiograms (Figure 3-14 A, B; lanes 3 – 7), which indicates PDK1-mediated transphosphorylation of UCN. To quantify UCN phosphorylation, I have measured the intensities of the autoradiograms and normalized to the intensities on the Coomassie brilliant blue (CBB) SDS polyacrylamide gels using ImageJ2/Fiji (Schneider et al. 2012, Schindelin et al. 2012, Schindelin et al. 2015). The results are depicted in Figure 3-14 C and D. Hence, I can show that PDK1-mediated in vitro phosphorylation is significantly decreased in absence of PIF motif but it is not essential in vitro.

Figure 3-14 In vitro kinase assays of active PDK1.1, PDK1.2 and five different UCN versions.

Coomassie brilliant blue (CBB)-stained gels and autoradiograms for PDK1.1 and PDK1.2, respectively, in combination with different UCN versions are demonstrated. Uppermost band depicts MBP:PKD1 (arrows) and lowermost band depicts GST:UCN $_x$ (arrowheads). (A) Lane 1 shows MBP:PDK1.1 and lane 2 shows GST:UCN autophosphorylation. Lanes 3 – 7 show combinations of MBP:PDK1.1 and the five UCN versions described in Figure 3-13. Please note absence of any signal in lanes 8 and 9 (GST:UCN G_{165S} and GST:UCN KD). (B) Lane 1 shows MBP:PDK1.2 and lane 2 shows GST:UCN autophosphorylation. Lanes 3 – 7 show combinations of MBP:PDK1.2 and the five UCN versions described in Please note presence of autophosphorylation in lane 8 (GST:UCN Δ PIF) and absence of any signal in lane 9 (GST:UCN KD/Δ PIF).

(C, D) UCN $_x$ phosphorylation intensity relative to CBB input in absence or presence of (C) MBP:PDK1.1 or (D) MBP:PDK1.2 is shown. Please note significant differences of

RESULTS

phosphorylation intensity in a PIF motif dependent manner (asterisks). P-values: (C) $p=0.031$, (D) $p=0.039$. Intensities were measured using ImageJ2/Fiji (Schneider et al. 2012, Schindelin et al. 2012, Schindelin et al. 2015). $N = 3$ (three independent expression-purification replicates and subsequent in vitro kinase assays).

To exclude influence of UCN autophosphorylation, I decided to compare relative UCN_x phosphorylation of GST:UCN_{KD} and GST:UCN_{KD/ΔPIF}. Both PDK1s phosphorylate GST:UCN_{KD/ΔPIF} significantly less strongly compared to GST:UCN_{KD}. Moreover, PDK1-mediated transphosphorylation of UCN is stronger than UCN autophosphorylation (Figure 3-14 C, D; compare UCN alone with PDK1 + UCN_{KD}).

Figure 3-15 In vitro kinase assays of inactive PDK1 and active UCN.

CBB gels and autoradiograms for PDK1.1^{KD} and PDK1.2^{KD}, respectively, combined with the five versions of UCN. (A) Lanes 1 and 2 show active PDK1.1 and active UCN, respectively, as controls. Lanes 4 – 8 show inactive PDK1.1 combined with either of the five UCN versions, and lane 9 shows PDK1.1^{KD} without UCN as a control. Please note the UCN-mediated transphosphorylation (asterisk) of PDK1.1^{KD} in combination with WT UCN and UCN^{ΔPIF}. (B) Lanes 1 and 2 show active PDK1.2 and active UCN, respectively, as controls. Lanes 4 – 8 show inactive PDK1.2 combined with either of the five UCN versions, and lane 9 shows PDK1.2^{KD} without UCN as a control. Please note the UCN-mediated trans-phosphorylation (asterisk) of PDK1.2^{KD} in combination with WT UCN and UCN^{ΔPIF}. Arrows indicate PDK1 and arrowheads indicate UCN. $N = 3$.

RESULTS

In order to test whether GST:UCN also phosphorylates MBP:PDK1 *in vitro*, I used the above described kinase deficient versions of PDK1s and analyzed their behavior in kinase assays in absence or presence of the five GST:UCN versions. Figure 3-15 shows that GST:UCN as well as GST:UCN Δ PIF phosphorylate both inactive MBP:PDK1 KD fusion proteins. To summarize, I demonstrate *in vitro* that the active MBP:PDK1 versions phosphorylate GST:UCN, that active GST:UCN versions phosphorylate kinase deficient versions of MBP:PDK1, and that UCN's PIF motif contributes to this interaction but it is not essential *in vitro*.

Furthermore, I was interested if the presence of GST:UCN influences MBP:PDK1 activity. Thus, I performed kinase assays using active MBP:PDK1.1 or MBP:PDK1.2, respectively, in combination with increasing amounts of either GST:UCN, GST:UCN G165S , or GST:UCN KD . As shown in Figure 3-16, the amount of MBP:PDK1.1 (A – C) and MBP:PDK1.2 (D – F) was kept constant (CBB gels, arrows) and GST:UCN was increased from lane 4 to lane 9 (CBB gels, arrowheads). I measured relative MBP:PDK1 phosphorylation intensities as described above. Figure 3-16 reveals that the determined MBP:PDK1 phosphorylation intensities relative to CBB input are constant in combinations with UCN G165S and UCN KD (Figure 3-16, B and C). In combination with active GST:UCN, both MBP:PDK1 phosphorylation intensities show a slight but significant decrease. The higher the GST:UCN level the lower were the measured MBP:PDK1 intensities (Figure 3-17A). The detected decrease in phosphorylation intensity was stronger for PDK1.2 than for PDK1.1.

These results suggest that high levels of active GST:UCN are able to repress PDK1 activity *in vitro*, whereas the two inactive versions do not significantly alter PDK1 activity.

RESULTS

Figure 3-16 Influence of increasing amounts of UCN on PDK1 activity.

CBB gels and autoradiograms for PDK1 and increasing amounts of either UCN, UCN_{G165S} or UCN_{KD}. (A) Constant levels of PDK1.1 with increasing amounts of UCN. (B) Constant levels of PDK1.1 with increasing amounts of UCN_{G165S}. (C) Constant levels of PDK1.1 with increasing amounts of UCN_{KD}. (D) Constant levels of PDK1.2 with increasing amounts of UCN. (E) Constant levels of PDK1.2 with increasing amounts of UCN_{G165S}. (F) Constant levels of PDK1.2 with increasing amounts of UCN_{KD}. Arrows indicate PDK1 and arrowheads indicate UCN_x. The first (A, B, D, E) or the second (C, F) lane shows PDK1 without UCN. The second (A, B, D, E) or the third (C, F) lane shows UCN auto-activity. Lanes 4 – 9 show PDK1 with increasing amounts of UCN_x (with lane 4 containing the lowest, and lane 9 the highest UCN_x amount; indicated by the grey triangles). N = 3.

RESULTS

Figure 3-17 Relative PDK1 phosphorylation with respect to UCN_x levels.

PDK1 phosphorylation relative to the CBB input dependent on the level of UCN_x is depicted. Triplicates for each combination shown in Figure 3-16 were measured using ImageJ/Fiji (Schneider et al. 2012, Schindelin et al. 2012, Schindelin et al. 2015). Please note the significant decrease in relative PDK1 phosphorylation dependent on active UCN (upper left; p-values for the highest compared to the lowest level of UCN: p(PDK1.1)=0.021, p(PDK1.2)=0.024). In presence of UCN_{KD} (upper right) or UCN_{G165S} (lower left) no decrease in relative PDK1 phosphorylation was observed. N = 3.

To gain deeper insights in the regulation of UCN, I was interested in detecting the PDK1-dependent UCN phosphorylation sites. Consequently, I performed 'cold' kinase assays and in collaboration with Dr. Fiona Pachl (Chair of Proteomics and Bioanalytics, Prof. Dr. B. Küster, TUM) proteins were analyzed in a liquid chromatography-mass spectrometry/mass spectrometry (LC-MS/MS) approach. Recovery of all peptides of UCN was only 47 – 51% but we were able to identify two phosphorylated serine residues (S233 and S242) within the activation segment of UCN. S242 represents the predicted serine in the T-loop necessarily phosphorylated for activation of the kinase (Figure 3-18). The second detected Ser residue (S233) represents probably the secondary phosphorylation site within the activation segment, which is known to contribute to the catalytic

RESULTS

activity of several AGC kinases (Nolen et al. 2004). The in vitro detected PDK1-dependent phosphorylation sites could be a first cue for PDK1-dependent activation of UCN.

Figure 3-18 PDK1-dependent UCN phosphorylation sites in vitro.

Two phosphorylated serine residues, namely S233 and S242, were detected in a LC-MS/MS approach in collaboration with Dr. Fiona Pachl and Dr. Peng Yu (Chair of Proteomic and Bioanalytics at TUM, Prof. Dr. B. Küster). Both Ser residues are located in the activation segment. S242 represents the conserved activation site in the T-loop.

3.2.3.3 Yeast two-hybrid assay

To substantiate the direct in vitro interactions between the PDK1 proteins and UCN, I performed yeast two-hybrid assays (Y2H). Therefore, I used the protein versions described in Figure 3-13 and section 3.2.3.2. PDK1 versions were fused to the activation domain (AD) and UCN versions were fused to the DNA-binding domain (DB) of the GAL4 transcription factor and co-transformed into yeast strain AH109. As shown in Figure 3-19, only yeast cells transformed with the WT versions of either PDK1 and WT UCN were able to grow on triple drop-out medium (SD-LWH) whereas on double drop-out medium (SD-LW; transformation control) yeast cells co-transformed with any AD – DB combination grew. The results showed that PDK1 (WT) and UCN (WT) proteins directly interact with each other in a Y2H assay. The controls with only AD or DB, respectively, did not grow on SD-LWH.

Figure 3-19 Yeast two-hybrid assay of AD:PDK1 versions combined with DB:UCN versions.

DB:UCN was tested with all four versions of PDK1, the other UCN versions were only tested with the wild type versions of PDK1. The left panel depicts yeast growth on transformation control plates (SD-LW), the right panel the interaction control plates (SD-LWH). Please note that only those yeast cells are able to grow on SD-LWH, which were co-transformed with DB:UCN and AD:PDK1.1 or AD:PDK1.2. AD: activation domain of GAL4 TF; DB: DNA-binding domain of GAL4 TF; SD-LW: SD medium lacking Leu and Trp (transformation control); SD-LWH: SD medium lacking Leu, Trp, and His (interaction control).

3.2.3.4 Bimolecular fluorescence complementation assay in Arabidopsis protoplasts

As a third different and independent method to show direct protein-protein interaction in a plant cell between the studied AGC kinases, I finally employed a bimolecular fluorescence complementation (BiFC; Split-YFP) assay in Arabidopsis mesophyll protoplasts. To this end, we cloned the protein versions described above (Figure 3-13; 3.2.3.2) into vectors pSPYNE or pSPYCE, respectively (Walter et al. 2004). PDK1 versions were fused to the N-terminal part (pSPYNE) and

RESULTS

UCN versions to the C-terminal (pSPYCE) part of YFP. Protoplasts were successfully isolated and transfected with either transfection control, pSK35S-GFP (Figure 3-20 A; gift from Chair of Botany (Prof. Dr. E. Grill), TUM), or different combinations of pSPYNE and pSPYCE (Figure 3-20, B – G), and analyzed using an Olympus FV1000 CLSM. Free GFP of transfection control was detected in the cytosol and the nucleus (A), YFP signals were detected in the cytosol (B, C). I detected YFP fluorescence only for the combinations PDK1.1:YFP^N – UCN:YFP^C and PDK1.2:YFP^N – UCN:YFP^C (Figure 3-20, B and C). All combinations with either a kinase deficient PDK1, a kinase deficient UCN (UCN_{G165S}, UCN_{KD}, UCN_{KD/ΔPIF}) or a PIF-deleted UCN (UCN_{ΔPIF} and UCN_{KD/ΔPIF}) did not exhibit any YFP signals (Figure 3-20, D and E; two examples are shown). The used negative controls, in which only YFP^C in combination with PDK1:YFP^N or only YFP^N in combination with UCN:YFP^C were combined, all showed no signal (Figure 3-20, F and G). This study in plant cells substantiates the beforehand executed studies in yeast and in vitro. I can clearly show that both PDK1 proteins interact with UCN in at least three independent assays (in vitro, in yeast, and in plant cells).

3.2.4 Relationship between *PDK1* and *ATS*

The negative regulation of PDK1 by UCN mimics the similar inhibition of *ATS* by UCN (Enugutti et al. 2012, Enugutti and Schneitz 2013). This raises the question how UCN, *ATS* and PDK1 relate to each other. In order to address this issue, I started to investigate the relationship between PDK1 and *ATS*. The *ATS* activation tagging line *sk21-D* described by Gao et al. (2010) overexpresses *ATS* in its normal expression domain. This leads to mild *ucn-1*-like protrusions in the integuments (Enugutti and Schneitz 2013). The combination *sk21-D ucn-1* results in an enhanced outgrowth (Enugutti and Schneitz 2013). In a first experiment, I crossed the *sk21-D* line with the *pdk1* KO lines described in section 3.1.3, and I analyzed double homozygous F3 offspring. I analyzed 346 ovules for *pdk1.1 sk21-D*, and 367 ovules for *pdk1.2 sk21-D*. Whereas 21 of 306 (6.8%) homozygous *sk21-D* ovules showed protrusion formation, none of the analyzed ovules in *pdk1 sk21-D* exhibited any protrusions (Figure 3-21). This genetic finding relates *ATS* to *PDK1* and suggests that PDK1 activity is required for protrusion formation in *ATS* overexpressors.

Figure 3-21 Confocal micrographs of mature ovules of (A) *sk21-D*, (B) *pdk1.1 sk21-D*, and (C) *pdk1.2 sk21-D*.

Ovules were stained according to the mPS-PI protocol (Truernit et al. 2008). Please note the protrusion in A (arrow) and absence of protrusions in B and C. Scale bars: 20 μm .

Since PDK1:EGFP localizes to the cytosol and to the PM, and ATS:YFP was only found to be present in the nucleus, direct in planta interaction between PDK1 and ATS is unlikely. In vitro kinase assays showed a very weak phosphorylation of ATS by PDK1 (not shown) but I could not confirm this interaction in BiFC assays in protoplasts (Figure 3-24, K). How exactly PDK1 and ATS relate to each other in planar growth control remains to be determined (see discussion, section 4.2.1).

3.3 UCN phosphorylates serine residues of ATS in vitro

UCN was shown to directly repress the transcription factor ATS (Enugutti et al. 2012, Enugutti and Schneitz 2013). I was interested to shed more light onto this interaction. Therefore, I performed 'cold' kinase assays, in which I incubated either GST:UCN or GST:UCN_{G165S} with a thioredoxin-6xHis tagged ATS(Trx:6xHis:ATS). Subsequently, the proteins were digested with trypsin (or pepsin) and analyzed in a LC-MS/MS approach for detection of potential phosphosites (performed in collaboration with Dr. Fiona Pachl and Dr. Peng Yu from the Chair of Proteomics and Bioanalytics, Prof. Dr. B. Küster, TUM). Unfortunately, recovery of ATS peptides was not satisfactory in three different approaches (trypsin or pepsin digestion, use of an inclusion list). Three phospho-serine residues were detected within the recovered peptides (S13, S92, S211; Figure 3-22). Peptides, which could not be recovered in MS analysis, contain another seven serine residues whose phospho-status remains unknown.

Figure 3-22 ATS phosphosites determined in a LC-MS/MS approach.

Three phosphorylated serine residues, namely S13, S92 and S211, were detected in a LC-MS/MS approach in collaboration with Dr. Fiona Pachl and Dr. Peng Yu (Chair of Proteomic and Bioanalytics at TUM, Prof. Dr. B. Küster). Unfortunately, ATS peptides harboring another seven Ser residues could not be recovered.

3.3.1 UCN still phosphorylates ATS-phosphomutants

Since we were not able to detect the remaining peptides in different approaches, I decided to substitute the three detected phospho-serine residues with alanine residues (phosphomutants) to test if UCN still interacts with those mutant proteins. Figure 3-23 shows that recombinant GST:UCN is able to phosphorylate recombinant Thioredoxin (Trx):6xHis:ATS (lane 1) as well as all ATS-phosphomutants (single mutants in lanes 3 – 5; double mutants in lanes 7 – 9; and triple phosphomutant in lane 10). I did not detect any obvious differences in phosphorylation intensity of those mutants compared to WT ATS. Other serine residues in the peptides not recovered seem to be phosphorylation targets for UCN *in vitro* as well.

3.3.2 UCN interacts with ATS-phosphomutants in plant cells

In order to test the relevance of the detected phospho-serine residues, I transformed *Arabidopsis* mesophyll protoplasts with BiFC constructs as described in section 3.2.3.4 using WT ATS and its phosphomutants fused to YFP^N and UCN versions fused to YFP^C. As shown in Figure 3-24 (A and J), neither ATS:YFP^N nor UCN:YFP^C display any YFP fluorescence complemented with only YFP^C or YFP^N, respectively (negative control). As published by Enugutti et al. (2012), ATS:YFP^N together with UCN:YFP^C gives a YFP signal in the nucleus (B). To elucidate if substitutions of the three ATS serine residues have any impact on the interaction with UCN, I tested all ATS single,

RESULTS

double and triple phosphomutants fused to YFP^N in combination with UCN:YFP^C (Figure 3-24, C – I). All these combinations depict the same behavior as the WT proteins showing YFP fluorescence exclusively in the nucleus. These results support the above-shown in vitro data meaning that either the detected phosphosites are an in vitro artifact or that UCN phosphorylates other residues besides the discovered ones.

Furthermore, I have tested if PDK1-related UCN mutations/deletions still lead to interactions with ATS (Figure 3-24, L – O). Here, I show that UCN ATS interaction in protoplasts is not PIF-dependent (L) but on UCN kinase activity (M – O). Without UCN PIF motif the YFP fluorescence still localized to the nucleus (L) but three kinase deficient UCN versions fused to YFP^C in combination with ATS:YFP^N did not display any fluorescence complementation (M – O). Since the PIF motif is supposed to be only crucial for the interaction between UCN and PDK1, no impact of PIF deletion on ATS UCN interaction was assumed. Additionally, I wanted to know whether ATS interacts directly with PDK1. In more than 800 protoplasts inspected, I was not able to detect any YFP fluorescence, neither in the nucleus nor in the cytosol (Figure 3-24, K).

Taken together, UCN directly represses ATS and PDK1 presumably in a similar posttranslational fashion. However, since a *pdk1* knockout rescues not only the integuments but also the flowers, PDK1 repression appears more global in comparison to ATS. Identification of PDK1 as a regulator of planar growth is a major breakthrough regarding the understanding of the UCN-mediated molecular mechanism coordinating cell division and growth in ovule integuments and other floral organs.

Figure 3-24 Bimolecular fluorescence complementation assays between UCN_x, PDK1 and ATS phosphomutants in Arabidopsis mesophyll protoplasts.

Protoplasts were co-transformed with pSPYNE:PDK1_x, pSPYNE:ATS, or pSPYNE_{ev}, respectively, and pSPYCE:UCN_x, pSPYCE:ATS, or pSPYCE_{ev}, respectively. (A – G) Confocal micrographs depicting YFP channel, chloroplast autofluorescence, DIC and merge (from left to right). (A + J) Negative controls. (B – I, K – O) BiFC combinations. The combinations are given on the left. Please note that all ATS phosphomutants with UCN show YFP signals in the nuclei (C – I), whereas absence of UCN kinase activity (M – O) does not lead to any fluorescence. The UCN PIF motif is not necessary for the interaction with ATS (L). Empty vector controls do not show YFP complementation (A, J). For all negative combinations at least 800 protoplasts were inspected. Scale bars: 5 μm. Figure continues on next page.

RESULTS

3.4 Generation of novel *ucn* alleles

Unfortunately, the second *ucn* allele (*ucn-10*) displaying strong *ucn-1*-like phenotypes has been lost. Moreover, the null allele *ucn-2* in Col-0 background exhibits morphological *ucn-1*-like phenotypes only under short day conditions. Therefore, I decided to utilize the CRISPR/Cas9 system to generate novel *ucn* alleles in order to obtain at least one additional independent *ucn* mutant allele. Therefore, I made use of the system developed by Wang et al. (2015), in which an egg cell specific promoter (*pEC1.2*) controls *Cas9* expression. The advantage of an egg cell specific over constitutive promoters (e.g., *pCaMV35S*, *pUBQ10*) is the occurrence of homozygous or trans-heterozygous mutations already in T1 generation rather than a genetic mosaic. Here, I present a novel *ucn* mutant, which I named *ucn-11*.

3.4.1 Approach

In order to try to mimic the *ucn-10* allele (D122N), I designed a single guide RNA (sgRNA) binding to the region +346 to +365 of the *UCN* coding sequence. The destination vector pHEE401 containing this sgRNA under control of the *U6-26* promoter and the plant optimized *Cas9* coding sequence under control of *pEC1.2* was transformed into *Ler* and Col-0 WT plants. Subsequently, I phenotypically analyzed the resulting T1 generation and sequenced the target region of three T1 plants (*Ler* background) showing a mild *ucn-1*-like phenotype.

3.4.2 Characterization of *ucn-11*

Phenotypic analysis of the resulting independent T1 plants suggested that three of them might contain a mutation in the *UCN* gene. In order to evaluate whether these three plants harbor a desired mutation, I sequenced the region of interest. For one plant, I obtained a mutated sequence besides the WT sequence indicating heterozygosity. The other two plants showed WT sequence. Subsequently, I cloned the amplicon featuring into pJET1.2/blunt and transformed the resulting vector into *E.coli*. Subsequently, I sequenced four clones. One of them contained a sequence distinct from WT sequence. This sequence depicted a single adenine insertion at position +386 leading eventually to a STOP codon at position +391 to +393 (Figure 3-25), and resulting in a protein of only 130 instead of 404 AA. The predicted mutant protein lacks the whole activation segment, the complete second kinase subdomain and 40 AA of kinase subdomain 1

RESULTS

making it most likely an inactive kinase. Molecular characterization of *ucn-11* needs to be performed in more detail.

The resulting phenotype is displayed in Figure 3-25. Compared to *ucn-1* (Figure 3-25, C), the novel *ucn-11* mutant shows weaker but conspicuous protrusions in ovules and floral distortion (Figure 3-25, B). To date, I have obtained more CRISPR-mediated mutants for other target regions of *UCN* and for the *PDK1* genes in *Ler* background, which need to be analyzed pheno- and genotypically.

To conclude, the utilized CRISPR/Cas9 system is functional and sufficient to obtain mutants in different target regions and results in expected phenotypes in case of *UCN*.

Figure 3-25 Stereo- and confocal micrographs depicting *ucn-11* phenotype, and *UCN* gene structure.

The upper panel depicts stereo-micrographs of flowers, the lower panel confocal micrographs of mPS-PI stained mature ovules. (A) *Ler* WT, (B) *ucn-11*, and (C) *ucn-1* phenotypes. Please note distorted flower and ovule protrusion (arrow) in *ucn-11* and *ucn-1*. Scale bars: (flowers) 1 mm; (ovules) 20 μ m. (D) Gene structure of *UCN* with CRISPR/Cas9 induced *ucn-11* single A insertion.

4 DISCUSSION

The spatiotemporal orchestration of proliferation and elongation is of paramount importance for the maintenance of distinct cell layers and tissue morphogenesis. Aberrant behavior of molecular components of this process can result in tumor formation (Weinberg 2014). Among various central cell cycle regulators in animals, several members of the AGC kinase family play key roles in tumor formation and cancer (Pearce et al. 2010). The most prominent AGC kinase with respect to the formation of tumors and cancerogenesis in animals is PDK1 (Gagliardi et al. 2017). By contrast, plants have evolved mechanisms that seem to maintain tissue architecture more robustly, as they appear relatively resistant to spontaneous or hereditary genetic tumor formation. The rigid cell wall that immobilizes plant cells prevents plants from developing cancer (Doonan and Sablowski 2010). Thus, the control of tissue architecture maintenance in plants is considered to vary from that in animals (Dodueva et al. 2007, Doonan and Sablowski 2010).

4.1 PDK1s – AGC master regulators of development?

AGC kinases play pivotal roles in animals as well as in plants. Many of them are involved in important developmental processes. Animal PDK1 is known as the master regulator of AGC kinase signaling by transducing signals from phospholipids as secondary messenger to the downstream AGC kinase targets, which subsequently initialize signaling pathways. *PDK1* genes are present in all eukaryotic kingdoms of life (Zegzouti et al. 2006a, Zegzouti et al. 2006b, Dittrich and Devarenne 2012), and plant PDK1 proteins are strongly conserved among angiosperms (Figure 3-2). PDK1 functions in animals, especially in mammals, in a more crucial fashion compared to Arabidopsis. Despite a broad expression range throughout development and tissues (Figure 3-3, Figure 3-6; sections 3.1.2, 3.1.4), Arabidopsis *PDK1* functions seem to be involved in specific developmental tasks, such as root hair growth (Anthony et al. 2004, supplemental Figure 7-3). Overexpression of *PDK1* results in strongly affected root hair growth (supplemental Figure 7-3; Anthony et al. (2004)) and aberrant floral organ development including petals and ovules (Figure 3-10). Here, I present a functional analysis of PDK1 with respect to different aspects of plant development and to *UCN* signaling.

4.1.1 Do other kinases substitute for the PDK1s?

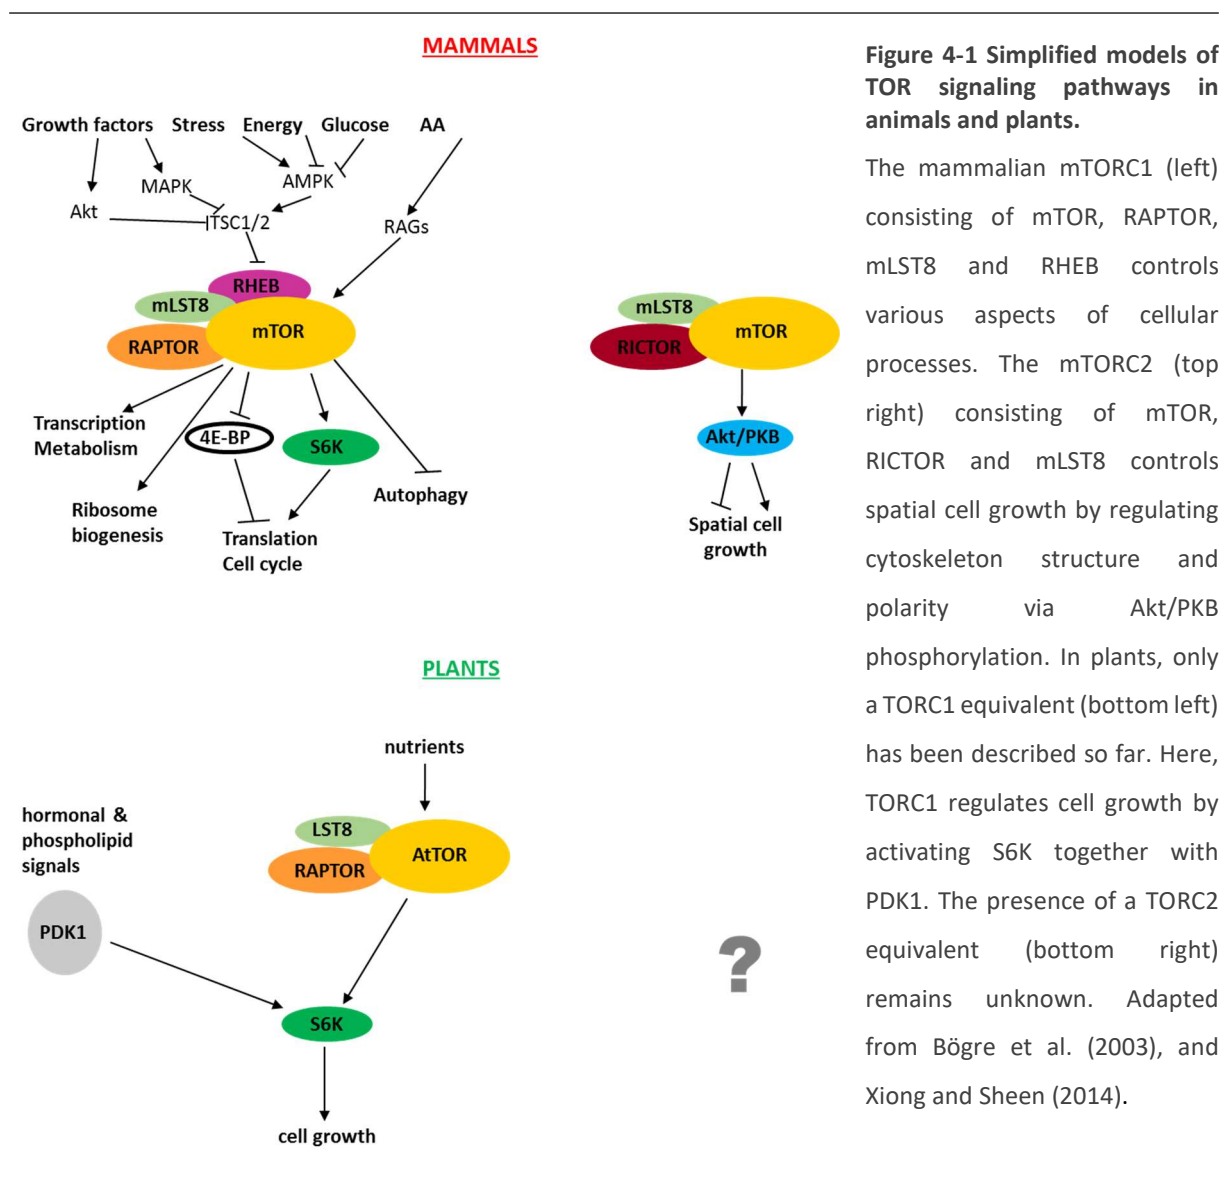

Since double knockout *pdk1.1 pdk1.2* plants show a very mild phenotype (Camehl et al. (2011), this study), the question was raised whether other kinases substitute PDK1's vital role (Zhang and McCormick 2009, Zulawski et al. 2014). By contrast, *PDK1* downregulation by 90% in mice led to 40 – 50% overall size reduction, and the knockout of *PDK1* resulted in abortion of the embryos at day 9.5 of embryo development (Lawlor et al. 2002), the double knockdown of tomato *PDK1s* is lethal as well (Devarenne et al. 2006), and *Physcomitrella patens PDK1* KO mosses exhibit strong developmental phenotypes and are severely impaired in abiotic stress resistance (Dittrich and Devarenne 2012). This leads to the hypothesis that the functions of *PDK1* in different species have evolved to distinct extents. In some species, *PDK1* is of essential importance for survival of the organism (Lawlor et al. 2002, Devarenne et al. 2006); in others the impact is more or less limited to distinct aspects of development (Matsui et al. 2010, Camehl et al. 2011, Dittrich and Devarenne 2012). The data regarding the nature of PDK1 proteins in plants show that they share common features (an activation segment including the Mg²⁺-binding site and the T-loop) and are very similar in size (Figure 3-2). The third predicted PDK1 (Zulawski et al. 2014) does not show any of these features (supplemental Figure 7-3). This clearly indicates that there is no evidence for At2g20050 representing a PDK1-like protein, and unfortunately, the authors of this study do not explain how and why they claim that At2g20050 should represent PDK1.3.

Accordingly, the question about the presence of other kinases substituting PDK1 function in pivotal processes of Arabidopsis development remain unanswered. In this study, I was also not able to find a good candidate as PDK1 substituent. BLAST approaches at NCBI and literature research were not sufficient to reveal any adequate candidate kinase.

Taking AGC kinase regulation in animals into account, the mammalian TARGET OF RAPAMYCIN (mTOR) kinase homolog could be involved in AGC kinase regulation in Arabidopsis as well (Figure 4-1). In mammals, TOR forms at least two functionally and structurally distinct complexes, mTORC1 and mTORC2 (Wullschleger et al. 2006, Laplante and Sabatini 2012, Cornu et al. 2013). The RAPTOR-mTOR complex (mTORC1) consists of several proteins including RAPTOR (regulatory associate protein of target of rapamycin), and is rapamycin sensitive. The second complex, mTORC2, which contains, among others, the RICTOR (rapamycin-insensitive companion of mTOR) protein, regulates spatial cell growth, by controlling cytoskeleton structure and polarity via phosphorylation of the AGC kinase Akt/PKB (Wullschleger et al. 2006, Laplante and Sabatini 2012, Cornu et al. 2013). Moreover, mTORC2 was shown to act as the elusive "PDK2" in the

DISCUSSION

regulation of Akt/PKB signaling (Sarbasov et al. 2005). In plants, the presence of a conserved and functional TORC1 complex was shown (Mahfouz et al. 2006, Moreau et al. 2012, Xiong and Sheen 2012, Xiong et al. 2013, Xiong and Sheen 2014). Although the presence of a TORC2 complex in plants has not been reported so far, it is hypothesized in several studies and reviews (Díaz-Troya et al. 2008, Moreau et al. 2010, Dobrenel et al. 2011, Moreau et al. 2012, Robaglia et al. 2012, Xiong and Sheen 2014). Arabidopsis *tor* mutants are embryo lethal, revealing the paramount importance of the TOR kinase as well in plants (Menand et al. 2002, Ren et al. 2012). Manipulating TOR kinase activity results in alterations in growth and development from embryogenesis to senescence (Menand et al. 2002, Deprost et al. 2007, Ren et al. 2011, Ren et al. 2012, Xiong and Sheen 2012, Caldana et al. 2013, Xiong et al. 2013).

4.1.2 PDK1 kinases control polarity in plant development

The AGC kinase PDK1 is involved in different aspects of plant development. In Arabidopsis, the most striking phenotypes I observed in overexpression lines rather than in knockout lines (Figure 3-4, Figure 3-10). As discussed above, *pdk1* double knockouts display very mild phenotypes but overexpressors for either PDK1 exhibit interesting phenotypes regarding floral organ development and root hair growth (supplemental Figure 7-4; Anthony et al. (2004). Root hairs in *PDK1_{ox}* show one to several branches or ballooning indicating polarity defects, and *pdk1* double KO lines are slightly impaired in root hair elongation. Anthony et al. (2004) demonstrated that OXI1/AGC2-1 is involved in root hair growth in a PA-PDK1-dependent manner. Thus, PDK1 might be required for correct polar growth. Polar growth is predominantly regulated via small RAC/ROP GTPases (Yalovsky et al. 2008). These small molecular switches control polar growth by cycling from an inactive GDP-bound state at the flanks of the tip to an active GTP-bound state at the apex of the tip-growing cell such as root hairs, pollen tubes or trichomes. For this regulation, other proteins are required, e.g. GAPs (GTPase-activating proteins), which catalyze the GTP-hydrolyzing activity of the GTPase; GDIs (GDP dissociation inhibitors), which are responsible to keep the non-plasma membrane-anchored GTPase in the inactive state. GEFs (Guanine nucleotide exchange factors), which are required to activate the inactive form by exchanging GDP for GTP. GDFs (GDI-displacement factor) are responsible to remove the GDI from the GDP-bound GTPase in order to facilitate binding to the membrane and replacing GDP by GTP, and downstream effectors, which are the targets of the active GTPase (reviewed, among others, in Kost (2008). In several studies, PDK1 was shown to be directly or indirectly involved in Rho GTPase signaling in animals (Flynn et al. 2000, Coleman et al. 2004, Pinner and Sahai 2008), and in plant innate immunity (Trusov et al. 2010). Similar PDK1-dependent mechanisms involving small RAC/ROP GTPases could explain the root hair phenotypes. PDK1 might regulate a downstream AGC kinase, which in turn interferes directly or indirectly with the tip-growth control machinery. Further experiments are required to elucidate the role of PDK1 in the control of tip-growth.

Furthermore, the *PDK1* transcripts and PDK1 proteins are abundant in all tissues during all developmental steps suggesting global functions of the PDK1s (Figures 3-3, 3-5, 3-8, 3-9). Interestingly, PDK1.2 localizes besides the cytosol as well to the plasma membrane of root cells in a polar fashion (apical-basal; Figure 3-9). Zegzouti et al. (2006a) demonstrated that PINOID (PID) interacts in vivo with PDK1, and that PDK1 increases PID activity. The polar localization of PDK1 might be due to the polar localization of the PIN localization modulators PID and D6PK (Zourelidou

et al. 2014), but PDK1 cannot play an important role in the recruitment and activation because *pdk1* double knockout plants do not show any phenotypes related to the disruption of polar auxin transport.

4.2 The role of *PDK1* in *UCN* signaling

I demonstrated that a single *pdk1* knockout is capable of restoring the *ucn-1* phenotype to 80 – 90% of the WT control (Figure 3-7). It was important to analyze high numbers of ovules because the homozygous offspring resulting from crossings between Col-0 and *ucn-1* (and reciprocal) rescue the *ucn-1* phenotype by about 20%. Initially, I was concerned that the genetic Col-0 background is responsible for the reduction of ovules depicting the *ucn-1* phenotype rather than the *pdk1* knockout. Subsequently, I analyzed more than 30,000 ovules in total. I analyzed three independent crossings for each combination (and reciprocal combinations), and three independent plants of homozygous F3 progeny of each crossing combination (Table 7-2 in supplement). In addition, *PDK1* overexpression lines exhibit an interesting *unicorn*-like phenotype in petals and ovule integuments (Figure 3-10). These results clearly indicate a role for *PDK1* in the control of planar growth and floral organ shape. PDK1 functions in animals and plants are similar but different. In animals, almost all AGC kinases are PDK1-dependent (Pearce et al. 2010). By contrast, the activity of several plant AGCVIII kinases is significantly increased by PDK1 in vitro but does not rely on the presence of PDK1 (Anthony et al. 2004, Devarenne et al. 2006, Zegzouti et al. 2006a, Enugutti et al. 2012). Additionally, at least in the species *Arabidopsis thaliana* and *Oryza sativa* (rice) the knockout of *PDK1* does not cause a dramatic phenotype (Matsui et al. 2010, Camehl et al. 2011) whereas in other species such as mouse and tomato loss of *PDK1* is lethal (Lawlor et al. 2002, Devarenne et al. 2006). One could ask whether *PDK1* is of any importance in *Arabidopsis*. The answer is obviously ‘yes’ although PDK1 functions in *Arabidopsis* seem to be more restricted to regulatory pathways of only some AGC kinases compared to other plant species and animals.

In animals, strong evidence is present that PDK1 is a major regulator of proliferation and growth. It has been demonstrated that overexpression of the *PDK1* gene or hyperactivity of the PDK1 protein is frequently involved in tumorigenesis via the AGC kinase Akt/PKB (Vivanco and Sawyers 2002, Carpten et al. 2007). Frequent amplification of the *PDK1* locus was shown in castration-resistant prostate cancer and lymph node metastases (Choucair et al. 2012), and *PDK1*

DISCUSSION

overexpression is related to acute myeloid leukemia (Zabkiewicz et al. 2014), melanoma (Scortegagna et al. 2014), hepatocellular carcinoma (Wang et al. 2016), and gastric cancer, in which the level of abundant PDK1 protein negatively correlates with patient prognosis (Bai et al. 2016). I showed that the expression levels of either *PDK1* in *Arabidopsis* correlate positively with the abundance of ovule protrusions up to certain levels (Figure 3-11). Thus, similarities between animal and plant *PDK1s* can be drawn. *PDK1* seems to be an important factor in animal and plant tumorigenesis. Interestingly, tumor formation in plants is usually related to alterations in cytokinin and auxin homeostasis (Morris 1986, Ulmasov et al. 1999, Remington et al. 2004, Doehlemann et al. 2008) but the *ucn*-induced protrusion formation is independent of auxin and cytokinin (Enugutti and Schneitz 2013). Accordingly, PDK1, with respect to *UCN* signaling, acts most likely independently of the before-mentioned hormones. In addition, *PDK1* function in floral organs is certainly not whorl- but organ-specific, since it affects the architecture of second whorl petals, the development of which is controlled by class A, B and E homeotic genes, and ovule architecture within the fourth whorl regulated by class C, D and E TFs. More evidence is provided by the fact that *PDK1*'s influence on floral organ development is most probably *UCN*-dependent, for which organ- and not whorl-specificity was shown by Enugutti and Schneitz (2013). Additionally, I provide evidence for a direct posttranslational PDK1 suppression mediated by UCN (Figures 3-10, 3-15 – 3-18). The genetics indicate that *UCN* is a negative regulator of *PDK1* (Figure 3-10), and active UCN is able to repress PDK1 activity in vitro (Figure 3-18). Since only active UCN is able to repress PDK1 in vitro, I propose a model in which PDK1 activates UCN, and UCN subsequently represses PDK1 in a negative feedback loop (Figure 4-2). Since PDK1 has been suggested to be constitutively active (Belham et al. 1999, Peterson and Schreiber 1999) PDK1 repression by another AGC kinase exhibits a unique feature. Although I have observed more interactions in vitro, the in vivo interaction data show clearly that UCN and PDK1 interact directly with each other in a kinase activity- and PIF-dependent manner.

Figure 4-2 Negative feedback loop of UCN activation and PDK1 repression.

In a first step, PDK1 activates UCN through phosphorylation, and the activated UCN represses PDK1 through phosphorylation in a second step. P indicates phosphate.

4.2.1 How does *PDK1* relate to *ATS* with respect to *UCN* signaling?

UNICORN was shown to suppress ectopic outgrowth in *Arabidopsis* ovule integuments by directly repressing the KANADI TF *ATS*. *PDK1* behaves similar to *ATS*. Thus, I was interested in elucidating whether *PDK1* regulates *ATS*. Therefore, I crossed the activation tagging line *sk21-D* (Gao et al. 2010), which overexpresses *ATS* in its own expression domain and therefore exhibits protrusions on ovule integuments (Enugutti et al. 2012, Enugutti and Schneitz 2013), with *pdk1.1* and *pdk1.2* KO lines. Interestingly, the homozygous offspring of these crossings showed no protrusion formation.

Next, I wanted to know whether *PDK1* and *ATS* proteins could interact directly. In vitro kinase assays first revealed very weak *PDK1*-dependent phosphorylation of *ATS* but BiFC assays in protoplast (Figure 3-24 K) could not support direct interaction. With respect to the subcellular localization of *PDK1* in the cytosol/at the plasma membrane and *ATS* in the nucleus (Figures 3-5, 3-6, and 3-24), direct interaction most probably does not occur. Thus, I propose a model, in which *ATS* positively influences the transcription of an unknown gene, the gene product of which is positively regulated directly or indirectly by *PDK1*. Both the *PDK1* proteins contribute to the activation of *UCN* but are not necessary in planta. I gained evidence for *PDK1*-dependent activation of *UCN* by phosphorylation site determination in *UCN_{KD}* proteins co-incubated with *PDK1.1* or *PDK1.2*, respectively (Figure 3-18). In collaboration with Dr. Fiona Pachl and Dr. Peng Yu (Chair of Proteomics and Bioanalytics, Prof. Dr. B. Küster, TUM), I determined two serine residues (S233 and S242) as in vitro target sites phosphorylated by both *PDK1*s. Interestingly, Dr. Julia Mergner (Chair of Proteomics and Bioanalytics, Prof. Dr. B. Küster, TUM) obtained the same serine residues in a large scale phosphoproteome analysis of in vivo samples (personal communication). These findings indicate that *PDK1* is able to activate *UCN*, and that the in vitro detected phosphorylation sites are not in vitro artifacts. These two serine residues are located in the activation segment of *UCN*. S242 represents the conserved Ser in the T-loop, the phosphorylation of which is essential for the activation of the kinase. S233 represents an additional conserved phosphorylation site in the activation segment, which is phosphorylated upon T-loop phosphorylation in a second step (Bögge et al. 2003, Pearce et al. 2010).

To gain further insights, these phosphorylation sites should be mutated to either Ala (phosphomutants) or Asp/Glu (phosphomimetics). Subsequently, the different combinations of the mutated *UCN* versions should be tested in different assays for interaction with *PDK1* and *ATS* (kinase assays, MST measurements, Y2H, BiFC) as well as transformed into different genotypes

DISCUSSION

(WT, *ucn-1*, *ucn-11*, *ucn-2*, *ats-3* and *pdk1 ucn-1* double mutants). The auto- and trans-activated UCN is translocated into the nucleus where it represses ATS that activates the expression of X, which I named *RHINO* (*RNO*) for the phenotypical relationship between unicorns and rhinoceroses. *RNO* mRNA is translated within the cytosol into protein RNO, the activity of which is positively regulated by the PDK1s. The hypothetical protein RNO in turn is a positive regulator of periclinal and/or a negative regulator of anticlinal cell division. Besides ATS suppression in the nucleus, UCN represses the PDK1 proteins in the cytoplasm and/or at the plasma membrane (Figure 4-3). Hence, I suppose a regulatory feedback between the three AGC kinases, UCN on the one and the two PDK1 proteins on the other hand. Loss-of-function of one of the *PDK1* genes is sufficient to restore the *ucn* phenotype almost to WT. Thus, either both PDK1 activities are needed for downstream signaling or we deal with a quantitative effect. Activation of the downstream effector(s) by only one PDK1 in both cases is not sufficient to result in the respective phenotype.

4.2.2 PDK1 as a global player in UCN signaling

Since ATS is restricted to the ovules, PDK1 is involved in the UCN-mediated repression of ectopic growth in a more global fashion. Loss of one of the two *PDK1* genes in *ucn-1* background rescues not only the integument phenotype but also the floral phenotype, i.e. aberrant growth in petals and stamens, and the overall morphological defects of the flower (Figure 3-7). These results indicate, together with the *PDK1* overexpression phenotypes (Figure 3-10), that PDK1 is part of *UCN* signaling in those floral organs, in which *UCN* controls organ architecture. Thus, I extended the above-introduced model of UCN-dependent regulation to other floral organs. The second model for the hypothetical molecular mechanism coordinating organ architecture in a UCN-dependent manner represents almost the same as described above for integument development. I just replaced the KANADI TF ATS by an unknown transcription factor named W (which might be a TF of the KANADI family as well). UCN is auto- and trans-activated by PDK1 in the cytosol/at the plasma membrane, and subsequently translocated to the nucleus where it represses W. The TF W is a positive regulator of *RNO* expression. The RNO protein is trans-activated by PDK1 in the cytosol/at the PM. UCN in turn negatively regulates PDK1 activity despite the hypothesis that PDK1 is due to its auto-activating ability constitutively active (Zhang and McCormick 2009). Here I present genetic and biochemical data obviously showing that PDK1 can be repressed by at least one AGCVIII kinase (Figures 3-9 and 3-16). The in vitro results I gained from the kinase assays in Figure 3-16 support a negative regulation of PDK1 by UCN. In a next step, the UCN-dependent

DISCUSSION

PDK1 phosphorylation sites need to be determined in order to gain deeper insights how UCN represses PDK1.

Figure 4-3 Hypothetical model of the molecular mechanisms underlying the UCN signaling pathway in the control of planar growth.

(A) Cartoon depicting the proposed molecular mechanism in the control of ovule integument architecture. UCN is activated in the cytosol, is translocated into the nucleus, where it represses ATS, which controls the expression of *RHINO* (*RHO*). The RHO protein is activated by PDK1.1 and PDK1.2 in the cytosol and induces periclinal divisions. (B) The same proposed molecular mechanism for the repression of ectopic growth in other floral organs. ATS is replaced by a yet unknown transcription factor W. Stars indicate phosphorylation. PA phosphatidic acid. Dotted arrows between PDK1 and UCN are not proven. Dash-dotted arrows indicate movement, and dashed

arrows indicate a proposed PDK1-mediated activation of the unknown factor RHO.

4.3 UCN-ATS interaction

In order to gain more insights into the UCN-dependent ATS regulation, I performed cold kinase assays, and the peptides resulting from protease (trypsin and pepsin, respectively) digestion were analyzed in LC-MS/MS approaches in collaboration with Dr. Fiona Pachl and Dr. Peng Yu (Chair of Proteomics and Bioanalytics, Prof. Dr. B. Küster, TUM). Although the recovery of the peptides was not complete, I obtained three phosphorylated Ser residues, namely S13, S92 and S211, reproducibly. Since changes in the experimental approach (using a different protease, application of an inclusion list) did not result in better recovery of the ATS peptides, I decided to generate Ser to Ala substitutions to obtain potential phospho-mutants of ATS. Testing all possible combinations of single, double and triple S to A substitutions in kinase and BiFC assays revealed that the detected phospho-serines are not sufficient. This might have different reasons. On the one hand, the in vitro phosphorylation sites might result from in vitro artifacts. On the other hand, the peptides that have not been recovered contain seven additional Ser residues, which might be of relevance regarding UCN-mediated ATS repression by phosphorylation. Therefore, one could try to analyze ATS phosphorylation sites in floral plant tissue of WT and *unicorn* mutants.

4.4 CRISPR/CAS9 mediated genetic engineering – a powerful tool for the generation of novel mutants

In order to generate a second *ucn* allele in *Ler* WT background, I made use of the CRISPR/Cas9 system using an egg cell specific promoter (*pEC1.2*) to drive *Cas9* expression (Wang et al. 2015). As described in section 3.4, I obtained one mutant so far that was named *ucn-11*. In principle, the used *Streptococcus pyogenes* Cas9 introduces double strand break (DSB) next to its PAM sequence (NGG), which needs to be adjacent to the target region. The repair of the introduced DSB by non-homologous end-joining (NHEJ) causes errors, which can be detected as deletions, insertions, and substitutions. Using an egg cell specific promoter has the major advantage over constitutive active promoter such as *pCaMV-35S*, *pUBQ* or *p16* that *Cas9* is exclusively expressed in the egg cell. Therefore, homozygous and trans-heterozygous mutants are expected already in T1 generation rather than a mosaic. I targeted a region of the *UCN* gene close to the lost *ucn-10* substitution (D122N) in order to try to mimic this mutation. I analyzed around 100 T1 plants phenotypically, and three of them showed a mild *ucn-1*-like floral phenotype.

DISCUSSION

Subsequent sequencing revealed that one of them carries an insertion of a single adenine at position +386 leading eventually to a STOP codon at position +391 to +393. This leads maximally to a protein of 130 instead of 404 AA, which in turn – if present and stable – lacking the whole activation segment, 40 AA of kinase subdomain 1, and the complete second kinase subdomain making it certainly an inactive kinase fragment. I observed in homozygous T2 offspring *unicorn* phenotypes in ovules, petals and overall floral architecture (see Figure 3-25), leading to the assumption that the used CRISPR/Cas9 system provided by Wang et al. (2015) is suitable for genome editing in my hands. To date, additional lines are in the pipeline for targeting the *UCN* gene directly downstream of the START codon in order to generate true null mutants in *Ler* and *Col-0*, as well as in *pdk1* single and double insertion lines. Moreover, I decided to knock out the *PDK1* genes (single and double KO) in *ucn* mutant backgrounds and *Ler* WT.

5 CONCLUSION

Organ architecture relies on spatiotemporal orchestration of proliferation, division plane determination and growth. Arabidopsis ovule integuments comprise excellent model tissues for studying planar growth control. The AGCVIII kinase UCN was demonstrated to be of paramount importance in the suppression of ectopic growth in floral organs (Enugutti et al. 2012). Furthermore, UCN-mediated direct repression of the KANADI transcription factor ATS was shown to be crucial for ectopic growth suppression. Besides ATS, no other components of the *UCN* signaling pathway have been identified so far.

3-PHOSPHOINOSITIDE-DEPENDENT KINASE 1 (PDK1) represents a major upstream regulator of AGC kinase signaling in animals, and for some AGC kinases as well in plants. Surprisingly, *pdk1.1 pdk1.2* double loss-of-function lines in Arabidopsis exhibit a quite mild phenotype but already a single *pdk1* loss-of-function in *ucn-1* rescues the *ucn* phenotype, which leads to the assumption that either both PDK1 activities are needed for activation of the downstream signaling or a simple quantitative effect leads to the phenotypical restoration. In fact, (over)expression of one *PDK1* in *pdk1.1 pdk1.2* double loss-of-function background is sufficient to compensate for the phenotype. Overexpression of one *PDK1* in WT background has the ability to phenocopy the *ucn-1* phenotype but to a lesser extent. Since PDK1 repression has not been shown so far, UCN-mediated PDK1 repression represents a novel and unique feature in AGC kinase regulation.

Since PDK1 and ATS were not supposed to interact directly due to their spatial separation (cytosol/plasma membrane vs. nucleus), and indeed, in BiFC assays in Arabidopsis protoplasts I could not observe YFP complementation indicating that these two proteins are strictly separated within the cell. Therefore, I propose a speculative model of the molecular mechanism underlying the *UCN* signaling pathway coordinating integument and floral organ architecture (Figure 4-3). The *UCN* kinase interacts with both PDK1 proteins in the cytosol and/or at the plasma membrane. Upon auto- and PDK1-dependent trans-phosphorylation, UCN is capable of entering the nucleus and repressing (i) ATS in ovule integuments; and (ii) an unknown transcription factor (maybe another KANADI TF) in petals for instance. In turn, these transcription factors, without being phosphorylated by UCN, activate the expression of another unexposed component I named *RHINO* (*RNO*). The *RNO* protein in turn is positively regulated by PDK1, which in turn is repressed by UCN.

CONCLUSION

UCN shares similarities with some animal AGC kinases and tumor-suppressors, e.g. Akt/PKB. *AtPDK1* shares common features with mammalian *PDK1s*, especially that PDK1 promotes protrusion formation in response to overexpression.

The overall analysis reveals that tumor or protrusion formation exhibits common characteristics between mammals and plants. PDK1 and at least one other AGC kinase are involved in this process in both kingdoms. Nevertheless, more components, especially *RNO*, need to be unraveled to gain a better understanding of the molecular mechanism underlying this process. The mechanism I propose shares some similarities with mechanisms described for AGC kinase-dependent growth control in animals (Akt/PKB; Warts/LATS). PDK1 seems to act as a master regulator that promotes cell proliferation across kingdoms.

In addition, further experiments are needed to completely understand the role of PDK1 in *UCN* signaling. Subcellular localization of PDK1:EGFP fusion proteins in *ucn-1* background are necessary to determine if the absence of functional UCN influences PDK1 distribution. Moreover, UCN S233/S242 phosphomutants need to be generated and analyzed in planta.

Figure 7-1 Alignment of 29 PDK1 protein sequences of 27 different plant species.

Black bars indicate identity or high similarity, grey bars similarity, and light grey value the less similarity. The brighter the grey value the less similar are the sequences. Lines show gaps. Alignment was performed in Geneious software using ClustalW algorithm with BLSM62 matrix. Sequences are continued on the next page.

SUPPLEMENT

Table 7-2 Absolute and relative values of *ucn-1* (*Ler*), *ucn-1* (*Col-0*), and *pdk1 ucn-1* ovule phenotypes.

Three individuals of three independent crosses for each combination were analyzed.

Figure 7-2 *PDK1.1*, *PDK1.2* and *ACT8* transcript amounts in *pdk1* T-DNA lines and Col-0.

The *pdk1* T-DNA lines do not contain the respective *PDK1* transcripts. *ACTIN8* was used as a control.

SUPPLEMENT

Figure 7-3 Root hair phenotypes.

Light micrographs of root hairs. (A) Phase contrast depicting *Ler* root hairs. (B – F) DIC images. (B – D) Three independent *PDK1* overexpressors. (E) *ucn-1* and (F) *pdk1.1 pdk1.2 ucn-1* triple mutant. Please note aberrant root hair polarity in B – E. Arrows indicate branching, arrowheads ballooning of the root hairs. The *pdk1* knockout rescues branching and ballooning of *ucn-1*. Scale bars: 20 μ m.

Figure 7-4 Protein alignment of PDK1.1, PDK1.2, and At2g20050.

The alignment was performed using ClustalW algorithm and BLOSUM62 matrix in Geneious software. The brighter the grey value the less similar are the sequences. Lines represent gaps. Please note that the black bars (AA 1 – 187, and 993 - 1094) are unique to At2g20050. The protein sequence analysis reveals that At2g20050 does not represent a third Arabidopsis PDK1, as claimed by Zulawski et al. (2014).

8 DANKSAGUNG

Zunächst möchte ich meinem Doktorvater Prof. Dr. Kay Schneitz herzlich für die Möglichkeit danken, dieses faszinierende Thema bearbeitet haben zu können. Außerdem für seine Unterstützung in vielerlei Hinsicht, sowie den Input durch wissenschaftliche Diskussionen und Anregungen. Kay hat mir die Möglichkeit gegeben, an einem spannenden Thema eigenverantwortlich zu arbeiten und den Grundstein für meine Karriere zu legen. Vielen Dank!

Des Weiteren danke ich Frau Prof. Dr. Brigitte Poppenberger-Sieberer für die Übernahme des Zweitgutachtens, und Herrn Prof. Dr. Erwin Grill für die Bereitschaft den Vorsitz der Kommission zu übernehmen.

Ich danke der gesamten AG Schneitz und ehemaligen Mitgliedern, mit denen man sich austauschen, Probleme erörtern oder einfach mal ein Bier trinken konnte. Besonderer Dank gilt unseren Technischen Assistentinnen Regina und Katrin für die Labororganisation, Pflanzenpflege, viele Stunden, Tage und Wochen des Klonierens und *In-situ*-Hybridisierens. Außerdem danke ich Prasad, Janys und Ajeet für anregenden wissenschaftlichen Austausch und Unterstützung, und allen anderen Mitgliedern des SNZ-Labs für die gute Arbeitsatmosphäre. Besonders möchte ich Susanna hervorheben, die durch ihre direkte, erfrischende Art seit Frühjahr 2016 als Sekretärin neuen Schwung mitgebracht hat, und für das ein oder andere Päuschen ;).

Außerdem danke ich den Mitarbeiterinnen und Mitarbeitern der Lehrstühle für Botanik und Systembiologie der Pflanzen für die gemeinsame Nutzung von Geräten und eine gute Arbeitsatmosphäre.

Außerordentlich dankbar und zufrieden bin ich damit, dass ich durch das Zusammentreffen mit einigen Menschen am Institut mittlerweile gute Freunde gewonnen habe, die ich nicht mehr missen möchte. Danke liebe *Botany Allstars and Friends*. Manche Menschen, die man im Leben trifft, vergisst man auch wieder, andere hinterlassen Spuren und Erinnerungen fürs ganze Leben. Namentlich sind hier zu nennen: Katha, mit der mich seit über 15 Jahren eine tiefe Freundschaft verbindet, die bisher trotz der großen räumlichen Distanz alles überdauert hat. Katja, Vio und Georg, mit denen ich seit Beginn des Biostudiums vor ziemlich genau 10 Jahren durch dick und dünn gehe und die immer für mich da sind. Co und co., die aus der Erlanger Zeit übriggeblieben sind. Steffi, Teresa, Moritz und meiner WG, die Freising von einem Kaff, in dem ich nicht sein wollte, zu einem Zuhause gemacht haben.

Meiner Familie, insbesondere meinen Eltern, bin ich sehr dankbar, dass sie mich immer unterstützt haben und es erst durch sie möglich geworden ist, dass ich jetzt hier sitze und meine Doktorarbeit mit dieser Danksagung beende.

Zum Wohle!

9 CURRICULUM VITAE

Persönliche Angaben

- | | |
|------------------------|------------|
| 1. Nachname | Scholz |
| 2. Vorname | Sebastian |
| 3. Geburtsdatum | 23.06.1987 |

|---------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| seit 11/2012 | Wissenschaftlicher Mitarbeiter, Professur für Entwicklungsbiologie der Pflanzen, TU München, Emil-Ramann-Str. 4, 85354 Freising. |
| 10/2010 – 09/2012 | Studium der Zell- und Molekularbiologie, Friedrich-Alexander-Universität Erlangen-Nürnberg.
Abschluss: Master of Science (M.Sc.) |
| 10/2007 – 09/2010 | Studium der Biologie (bis 03/2009 in Verbindung mit Chemie), FAU Erlangen-Nürnberg.
Abschluss: Bachelor of Science (B.Sc.) |
| 10/2006 – 09/2007 | Studium der Humanmedizin, FAU Erlangen-Nürnberg |
| 23.06.2006 | Allgemeine Hochschulreife (Abitur), Gymnasium Schloss Wittgenstein |
| 7. Titel der Dissertation | Regulatory feedback between AGC kinases coordinating Arabidopsis ovule integument growth. |
| 8. Betreuer | Prof. Dr. Kay Schneitz |
| 9. Publikationen | 1. LE BAIL A, <u>SCHOLZ S</u> , AND KOST B. 2013. Evaluation of reference genes for RT qPCR analyses of structure-specific and hormone regulated gene expression in <i>Physcomitrella patens</i> gametophytes. PloS one 8: e70998.

2. VADDEPALLI P, <u>SCHOLZ S</u> , AND SCHNEITZ K. 2015. Pattern formation during early floral development. Curr Opin Genet Dev 32: 16-23. |
