Set-Based Prediction of Pedestrians in Urban Environments Considering Formalized Traffic Rules

Markus Koschi¹, Christian Pek¹,², Mona Beikirch¹,², and Matthias Althoff¹

Abstract—Set-based predictions can ensure the safety of planned motions, since they provide a bounded region which includes all possible future states of nondeterministic models of other traffic participants. However, while autonomous vehicles are tested in urban environments, a set-based prediction tailored to pedestrians does not exist yet. This paper addresses this problem and presents an approach for set-based predictions of pedestrians using reachability analysis. We obtain tight over-approximations of pedestrians’ reachable occupancy by incorporating the dynamics of pedestrians, contextual information, and traffic rules. In addition, since pedestrians often disregard traffic rules, our constraints automatically adapt so that such behaviors are included in the prediction. Using datasets of recorded pedestrians, we validate our proposed method and demonstrate its use for evasive maneuver planning of automated vehicles.

I. INTRODUCTION

A. Motivation

Automated vehicles may endanger other traffic participants in the event that they misjudge a traffic situation. In urban environments in particular, vulnerable road users such as pedestrians impose strict safety requirements. For example, if autonomous vehicles do not consider that an approaching pedestrian might try to cross the road at the last second (cf. Fig. 1), a fatal collision could be inevitable.

To prevent such situations at an early stage, the future motion of pedestrians needs to be accurately predicted [1], [2]. Current probabilistic approaches are limited when predicting all feasible and legal future motion, since they are not designed to enclose all behaviors given an uncertain pedestrian model. In contrast, set-based predictions guarantee that all planned motions are safe, even when traffic participants deviate from the most likely prediction [3]. Recently, a prediction approach using reachability analysis to account for any feasible future motion of other traffic participants in a set-based fashion was proposed [4]. However, a set-based prediction method for pedestrians considering both structured and unstructured environments does not yet exist, making it difficult to provide advanced safety systems which ensure the safety of vulnerable road users.

Fig. 1. The safety of the ego vehicle’s planned motions can be guaranteed for given model assumptions by predicting all possible future behaviors of the pedestrian, which may include crossing the road even when traffic rules (e.g., a red light for the pedestrian) forbid such behavior.

B. Related Work

We review existing work on pedestrian prediction for automated vehicles in unknown environments categorized by whether they compute a) a single behavior, b) a probability distribution of multiple behaviors, or c) a bounded set of future behaviors. In order to apply such predictions, we require the current state of pedestrians from sensor data, which can be obtained as described in [5]–[7]; however, this process itself is beyond the scope of this work.

a) Single behavior: The probability of whether pedestrians intend to cross the roadway is computed in [8]–[12] using one or more of the following sources: motion information (previous path and current position), situation awareness (e.g., head pose), and contextual information (e.g., proximity to curb or intersection). Based on the predicted intention, the most likely behavior can be inferred, while other works directly compute a single trajectory [13], [14] or the time until the pedestrian will most likely cross [15].

b) Probability distribution: Predicting only a single behavior may suffice for short-term prediction; however, since many possible maneuvers exist, it is beneficial to compute a probability distribution of future behaviors by considering the possible goals of pedestrians [16]–[20].

c) Set of future behaviors: To verify that one does not collide with a pedestrian, a bounded set containing its possible future behaviors must be considered. While dynamic-based models have been used in [21]–[23], set-based models which integrate map-based information or traffic rules have not yet been developed, to the best of our knowledge.
C. Contribution

This paper significantly extends previous work on set-based predictions [4], [23] by considering not only motorized traffic participants but also pedestrians, while exploiting traffic rules based on the given environment map. This extension will be available in the next version of our open-source prediction tool SPOT. More specifically, our method is the first that can:

1) predict the feasible future motion of pedestrians in a formal and set-based manner,
2) obtain tight over-approximative occupancies by making use of formalized traffic rules and contextual information,
3) explicitly consider measurement uncertainties in the initial state of pedestrians, and
4) guarantee the safety of planned motions according to our assumptions.

The remainder of this paper is organized as follows. Sec. II introduces the required models and definitions, and Sec. III explains the set-based prediction of pedestrians. Sec. IV demonstrates our approach by using different datasets of recorded pedestrians and by evasive planning for autonomous vehicles. Finally, Sec. V concludes the paper.

II. PRELIMINARIES

A. Road Model

We model our environment in $\mathbb{R}^2$ using lanelets, which are atomic, interconnected, and drivable road segments [24]. Lanelets are defined using a left and right bound represented by a linearly interpolated list of points. As Fig. 1 shows, we distinguish two types of lanelets: vehicular lanelets (i.e., roadways) and pedestrian lanelets (i.e., sidewalks/pavements and crossings).

Definition 1 (Road networks)

We define the following types of road networks:

- The vehicular network is the union of all vehicular lanelets and is denoted by $W_{veh} \subseteq \mathbb{R}^2$.
- The pedestrian network $W_{ped} \subseteq \mathbb{R}^2$ is the union of all pedestrian lanelets, i.e., sidewalks $W_{side}$ and crossings $W_{cross}$. We use $W_{cross}(t)$ to denote the crossings a pedestrian is allowed to cross at time $t$ (cf. Sec. III).
- The forbidden network $W_{forbid} := W_{veh} \cap W_{ped}^c$ is the part of $W_{ped}$ pedestrians are not allowed to enter (where $W_{ped}^c$ denotes the complement of $W_{ped}$, cf. Fig. 4). The boundary of $W_{forbid}$ is denoted by $\partial W_{forbid}$.

Let a disk, i.e., a circular area, with center $[c_x, c_y]^T$ and radius $r$ be denoted as $C([c_x, c_y]^T, r) := \{(s_x, s_y)^T \mid (s_x - c_x)^2 + (s_y - c_y)^2 \leq r^2\}$. If $c_x = c_y = 0$, we just write $C(r)$.

The following predicates are defined using first-order logic to argue about the position of pedestrians:

1) predict the feasible future motion of pedestrians in a formal and set-based manner,
2) obtain tight over-approximative occupancies by making use of formalized traffic rules and contextual information,
3) explicitly consider measurement uncertainties in the initial state of pedestrians, and
4) guarantee the safety of planned motions according to our assumptions.

The remainder of this paper is organized as follows. Sec. II introduces the required models and definitions, and Sec. III explains the set-based prediction of pedestrians. Sec. IV demonstrates our approach by using different datasets of recorded pedestrians and by evasive planning for autonomous vehicles. Finally, Sec. V concludes the paper.

A. Road Model

We model our environment in $\mathbb{R}^2$ using lanelets, which are atomic, interconnected, and drivable road segments [24]. Lanelets are defined using a left and right bound represented by a linearly interpolated list of points. As Fig. 1 shows, we distinguish two types of lanelets: vehicular lanelets (i.e., roadways) and pedestrian lanelets (i.e., sidewalks/pavements and crossings).

Definition 1 (Road networks)

We define the following types of road networks:

- The vehicular network is the union of all vehicular lanelets and is denoted by $W_{veh} \subseteq \mathbb{R}^2$.
- The pedestrian network $W_{ped} \subseteq \mathbb{R}^2$ is the union of all pedestrian lanelets, i.e., sidewalks $W_{side}$ and crossings $W_{cross}$. We use $W_{cross}(t)$ to denote the crossings a pedestrian is allowed to cross at time $t$ (cf. Sec. III).
- The forbidden network $W_{forbid} := W_{veh} \cap W_{ped}^c$ is the part of $W_{ped}$ pedestrians are not allowed to enter (where $W_{ped}^c$ denotes the complement of $W_{ped}$, cf. Fig. 4). The boundary of $W_{forbid}$ is denoted by $\partial W_{forbid}$.

Let a disk, i.e., a circular area, with center $[c_x, c_y]^T$ and radius $r$ be denoted as $C([c_x, c_y]^T, r) := \{(s_x, s_y)^T \mid (s_x - c_x)^2 + (s_y - c_y)^2 \leq r^2\}$. If $c_x = c_y = 0$, we just write $C(r)$.

The following predicates are defined using first-order logic to argue about the position of pedestrians:

Definition 2 (Not intruding $W_{forbid}$)

The predicate $\text{notInWf}(X_s, r)$ evaluates to true if all points $(s_x, s_y)^T \in X_s \subseteq \mathbb{R}^2$ intrude the vehicular network by at most the distance $r$:

$$\text{notInWf}(X_s, r) \Leftrightarrow (W_{forbid} \cap C(r)) \cap X_s = \emptyset,$$

where $\cap$ denotes the Minkowski difference defined for sets $A$ and $B$ as $A \cap B := (A^c \cup B)^c$ using the Minkowski addition $(A \oplus B := \{a + b \mid a \in A, b \in B\})$.

Definition 3 (Conforming to crossing priority)

The predicate $\text{confPrio}(X_s, t)$ evaluates to true if none of the points $(s_x, s_y)^T \in X_s$ are located in a forbidden crossing at time $t$:

$$\text{confPrio}(X_s, t) \Leftrightarrow W_{cross} \cap W_{cross}^c(t) \cap X_s = \emptyset.$$

B. Reachable Set of Pedestrians

The motion of a pedestrian can be described by the differential equation

$$\dot{x}(t) = f(x(t), u(t)),$$

where $x \in \mathbb{R}^n$ is the state, $u \in \mathbb{R}^m$ is the input, and $t$ is the time. The possible states and inputs are bounded by the sets $X$ and $U$, respectively. We denote the initial time by $t_0$, the final time by $t_f > t_0$, an input trajectory by $u(\cdot)$, and a possible solution of (1) at time $t$ by $\chi(t, x(t_0), u(\cdot))$.

Definition 4 (Reachable set)

The reachable set $R \subseteq X$ of (1) is the set of states which are reachable at time $t$ from an initial set $X^0 \subseteq X$ at time $t_0$ and subject to the set of inputs $U$:

$$R(t) = \left\{ \chi(t, x(t_0), u(\cdot)) \mid x(t_0) \in X^0, \forall t^* \in [t_0, t] : \chi(t^*, x(t_0), u(\cdot)) \in X, u(t^*) \in U \right\}.$$ 

Our state vector is $x = [s_x, s_y, v_x, v_y]^T$, where $s_x$ and $s_y$ denote the position, $v_x$ and $v_y$ the velocity, each in $x$- and $y$-direction, respectively. We define the occupancy of a state as:

Definition 5 (Occupancy of a state)

The operator $\text{occ}(x)$ returns the set of points in the two-dimensional Cartesian space occupied by the pedestrian in state $x$ due to its circular dimensions with radius $r_{ped}$:

$$\text{occ}(x) := \{Px \oplus C(r_{ped})\},$$

where $P$ is the projection matrix $P = [I \ 0] \in \mathbb{R}^{2 \times 4}$, $I$ the identity matrix, and $0$ a matrix of zeros, both with proper dimensions. Given a set of states $X$, the operator is defined as $\text{occ}(X) := \{\text{occ}(x) \mid x \in X\}$.

To obtain the future occupancy of pedestrians efficiently, we over-approximate their reachable occupancy:

Definition 6 (Over-approximative occupancy set)

Based on Def. 4 and Def. 5, the occupancy set $\mathcal{O}(t)$ over-approximates the set of occupied points which are reachable by the pedestrian: $\mathcal{O}(t) \supseteq \text{occ}(R(t))$. 

1 Available at spot.in.tum.de
Since an occupancy \( \mathcal{O}(t) \) can be non-convex, we represent it by a polygon, and since a collision check with the intended trajectory of the ego vehicle requires an infinite number of points in time to be checked, we compute occupancies for consecutive time intervals \( \tau_k = [t_k, t_{k+1}] \subseteq [t_0, t_f] \) with time step size \( \Delta t = t_{k+1} - t_k \).

The initial set \( \mathcal{X}^0 \) in Def. 4 contains measurement uncertainties. Using a polar coordinate system to describe \( v_x \) and \( v_y \) by the radius \( v \) and the polar angle \( \varphi \), we introduce the following initial sets:

\[
\mathcal{X}^0_x := C(s_0, \Delta_x),
\]
\[
\mathcal{X}^0_y := [v_0 - \Delta_v, v_0 + \Delta_v],
\]
\[
\mathcal{X}^0_{\varphi} := [\varphi_0 - \Delta_{\varphi}, \varphi_0 + \Delta_{\varphi}],
\]

where \( s_0 := [s_{x0}, s_{y0}]^T \), and \( \Delta_x, \Delta_v, \) and \( \Delta_{\varphi} \) denote the measurement uncertainty of the corresponding variable. As Fig. 2 shows, the set of initial velocities is bounded by an annulus sector. The initial set \( \mathcal{X}^0 \) is constructed by the Cartesian product of the partial initial sets \( \mathcal{X}^0 := \mathcal{X}^0_x \times \mathcal{X}^0_y \times \mathcal{X}^0_{\varphi} \); the set \( \mathcal{X}^0 \) in Cartesian coordinates is denoted by \( \mathcal{X}^0 \).

The initial occupancy is \( \mathcal{O}^0 := \text{occ}(\mathcal{X}^0) \), which accounts for uncertainties in the pedestrian’s dimensions by choosing \( r_{\text{ped}} \) as the maximum of the measured radii.

III. PREDICTION OF PEDESTRIANS

To efficiently compute a tight over-approximative occupancy of (1), we use two types of occupancies: 1) the occupancy \( \mathcal{O}_{\text{dyn}}(t) \) considering the dynamics of the pedestrian and 2) the occupancy \( \mathcal{O}_{\text{rule}}(t) \) considering possible states according to traffic rules, as described in Sec. III-A and Sec. III-B, respectively. Then, the over-approximative occupancy is the intersection of both over-approximations:

\[
\forall \tau_k \subseteq [t_0, t_f] : \mathcal{O}(\tau_k) = \mathcal{O}_{\text{dyn}}(\tau_k) \cap \mathcal{O}_{\text{rule}}(\tau_k).
\]

A. Dynamic-Based Occupancy

We use a kinematic model for pedestrians:

**Definition 7 (Dynamic model of pedestrians)**

The dynamics of a pedestrian are described by a velocity- and acceleration-bounded point mass:

\[
\begin{align*}
\dot{x}_v &= u_x, & \dot{y}_v &= u_y, \\
\sqrt{|u_x|^2 + |u_y|^2} &\leq a_{\text{max}}, \\
\sqrt{|v_x|^2 + |v_y|^2} &\leq v_{\text{max}},
\end{align*}
\]

where \( u_x \) and \( u_y \) denote the acceleration input in the \( x- \) and \( y- \) direction, respectively, \( a_{\text{max}} \) the maximum allowed acceleration, and \( v_{\text{max}} \) the maximum allowed velocity.

To efficiently obtain the occupancy, we do not directly perform reachability analysis on (6), but use the approach proposed by [23]: We separately compute an acceleration-constrained occupancy \( \mathcal{O}_{\text{acc}}(t) \) considering only the constraint (6b) and a velocity-constrained occupancy \( \mathcal{O}_{\text{vel}}(t) \) considering only the constraint (6c), as explained in Sec. III-A.1 and III-A.2, respectively.

1) Acceleration-constrained occupancy:

**Proposition 1 (Reachable positions \( \mathcal{R}^\text{pos}_{\text{acc}}(t) \) for point in time)**

The reachable positions \( \mathcal{R}^\text{pos}_{\text{acc}}(t) \) of (6a) with (6b) are

\[
\mathcal{R}^\text{pos}_{\text{acc}}(t) = \Gamma_{\text{hom}}(t)\mathcal{X}^0 \oplus \Gamma_{\text{inp}}(t)\mathcal{U},
\]

where

\[
\Gamma_{\text{hom}}(t) := \begin{bmatrix} 1 & 0 & t & 0 \\ 0 & 1 & 0 & t \end{bmatrix}, \quad \Gamma_{\text{inp}}(t) := \frac{1}{2} t^2 \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}.
\]

**Proof:**

Let us first write (6a) in state-space form:

\[
\begin{bmatrix}
\dot{s}_x \\
\dot{s}_y \\
\dot{u}_x \\
\dot{u}_y
\end{bmatrix} =
\begin{bmatrix}
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0
\end{bmatrix}
\begin{bmatrix}
s_x \\
s_y \\
u_x \\
u_y
\end{bmatrix} +
\begin{bmatrix}
0 \\
0 \\
u_x \\
u_y
\end{bmatrix}.
\]

In general, the exact reachable set of linear systems cannot be computed, except for when \( A \) is nilpotent or the eigenvalues are purely real or imaginary [25]. Since \( A \) is nilpotent \((A^2)\) is a matrix of zeros), we can compute the exact reachable set as presented in [26, Sec. 3.2]:

\[
\mathcal{R}_{\text{acc}}(t) = e^{At}\mathcal{X}^0 \oplus \bigoplus_{i=0}^{\infty} \frac{A^i t^{i+1}}{(i+1)!} \mathcal{U}
\]

where

\[
\text{nilpotence} = (I + At)\mathcal{X}^0 \oplus (\mathcal{U}t) \oplus \frac{1}{2} At^2 \mathcal{U}.
\]

Since we are only interested in the reachable set of the positions, we multiply the above solution with the projection
Due to the nilpotence of $A$ for a time interval $\tau_k$, it is necessary to compute this occupancy depending on the intended motion of the ego vehicle.

Next, we consider the reachable set for time intervals.

**Proposition 2** (Reachable positions $R_{\text{acc}}(\tau_k)$ for time interval

The reachable positions of the acceleration-bounded model for a time interval $\tau_k = [t_k, t_{k+1}]$ are

\[ R_{\text{acc}}(\tau_k) = \text{conv}(\Gamma_{\text{hom}}(t_k), \Gamma_{\text{hom}}(t_{k+1})) \cup \Gamma_{\text{acc}}(t_k) \cup \Gamma_{\text{acc}}(t_{k+1}) \]

where $\text{conv}(A, B)$ returns the convex hull of the sets $A$ and $B$.

**Proof:** The proof follows directly from [27, Alg. 1], where the matrix $F$ in that algorithm is a matrix of zeros due to the nilpotence of $A$.

Finally, the acceleration-constrained occupancy for a single point in time is $\mathcal{O}_{\text{acc}}(t) = \text{occ}(R_{\text{acc}}(t))$ and $\mathcal{O}_{\text{acc}}(\tau_k) = \text{occ}(R_{\text{acc}}(\tau_k))$ for a time interval.

2) Velocity-constrained occupancy: Up until now, we have ignored the maximum velocity constraint in (6c). Let us first determine the earliest point in time when the maximum velocity is reached:

\[ v_{\text{max}} = v_0 + \Delta_v + a_{\text{max}} t_{\text{max}} \Leftrightarrow t_{\text{max}} = \frac{v_{\text{max}} - (v_0 + \Delta_v)}{a_{\text{max}}} \]

When starting at the origin with the maximum velocity in all directions, the reachable set is a disk centered at the origin with radius $v_{\text{max}}(t - t_{\text{max}})$. Thus, an over-approximation of the reachable positions considering the velocity constraint for $t > t_{\text{max}}$ is

\[ \mathcal{O}_{\text{vel}}(t) = \mathcal{O}_{\text{acc}}(t_{\text{max}}) \cup \mathcal{O}(v_{\text{max}}(t - t_{\text{max}})) \]

Due to the monotonic growth of $\mathcal{C}(v_{\text{max}}(t - t_{\text{max}}))$, it follows that $\mathcal{C}(v_{\text{max}}(t_{k+1} - t_{\text{max}})) \supseteq \mathcal{C}(v_{\text{max}}(t_k - t_{\text{max}}))$, and thus

\[ \mathcal{O}_{\text{vel}}(\tau_k) = \mathcal{O}_{\text{acc}}(t_{\text{max}}) \cup \mathcal{O}(v_{\text{max}}(t_{k+1} - t_{\text{max}})) \]

Since $\mathcal{O}_{\text{vel}}(t)$ is not required for $t \leq t_{\text{max}}$, the overall dynamic-based occupancy is

\[ \mathcal{O}_{\text{dyn}}(\tau_k) = \begin{cases} \mathcal{O}_{\text{acc}}(\tau_k), & t_k \leq t_{\text{max}}; \\ \mathcal{O}_{\text{acc}}(\tau_k) \cap \mathcal{O}_{\text{vel}}(\tau_k), & t_k > t_{\text{max}}. \end{cases} \]

**B. Rule-Based Occupancy**

We incorporate formalized traffic rules into our prediction [28]. As a legal source, we use the Vienna Convention on Road Traffic [29]. We assume that pedestrians adhere to traffic rules and do not obstruct vehicular traffic [29, 7§1]. However, if pedestrians violate rules, we have to take necessary precautions to avoid endangering pedestrians [29, 21§1].

Pedestrians are generally not allowed to leave the pedestrian network and enter the roadway [29, 20§2]. Since this rule has different cases of violations, we deduce four atomic constraints described in Tab. I these constraints each have a Boolean variable, denoted by $b$, which allows us to enable and disable this constraint individually.

The occupancies resulting from these constraints are illustrated in Fig. 4 and are computed as presented in Tab. I where we use the following variables: The distance required

<table>
<thead>
<tr>
<th>Constraint</th>
<th>Boolean</th>
<th>Description</th>
<th>Traffic rule [29]</th>
<th>Occupancy</th>
</tr>
</thead>
<tbody>
<tr>
<td>$C_{\text{prio}}$</td>
<td>$b_{\text{prio}}$</td>
<td>Within $\mathcal{W}_{\text{cross}}$, pedestrians are allowed to cross if they have priority over vehicular traffic, i.e., at pedestrian crossings, at intersections when pedestrians have green traffic lights, and at intersections without traffic lights when vehicles take a turn.</td>
<td>20§6(b), 21§2</td>
<td>$\mathcal{O}<em>{\text{prio}}(t) = \begin{cases} \mathcal{W}</em>{\text{cross}}(t), &amp; b_{\text{prio}}; \ \varnothing, &amp; \neg b_{\text{prio}}. \end{cases}$</td>
</tr>
<tr>
<td>$C_{\text{stop}}$</td>
<td>$b_{\text{stop}}$</td>
<td>When (carelessly) stepping on the roadway outside $\mathcal{W}<em>{\text{cross}}$ (i.e., onto $\mathcal{W}</em>{\text{forbid}}$), the pedestrian immediately slows down with $\alpha_{\text{stop}}$ to come to a stop as soon as possible in order not to impede vehicular traffic.</td>
<td>20§6(a,c)</td>
<td>$\mathcal{O}<em>{\text{stop}} = \begin{cases} 0, &amp; \mathcal{C}(s_0, r</em>{\text{stop}} + p_{\text{ped}}), \neg b_{\text{stop}} \land \text{notInW}(O^0, 0); \ \mathcal{C}(p_{\text{V}}(s_0), r_{\text{stop}} + p_{\text{ped}}), \neg b_{\text{stop}} \land \neg \text{notInW}(O^0, 0). \end{cases}$</td>

<td>Walking on the roadway is not allowed; $\mathcal{W}<em>{\text{forbid}}$ may be entered by the margin $\xi</em>{\text{slack}}$ only if no usable sidewalk is provided.</td>
<td>20§2(a), 20§3, 20§4</td>
<td>$\mathcal{O}<em>{\text{slack}} = \begin{cases} 0, &amp; (\mathcal{W}</em>{\text{forbid}} \oplus C(\xi_{\text{slack}})) \cap \mathcal{W}<em>{\text{forbid}}, b</em>{\text{slack}}; \ \varnothing, &amp; \neg b_{\text{slack}}. \end{cases}$</td>
</tr>
</tbody>
</table>

TABLE I

**Definition of the occupancies based on formalized traffic rules, which are computed depending on their Boolean variable.**
Note that all partial occupancies of \( \mathcal{O}_{\text{rule}}(t) \) are constant over the prediction horizon, and \( \mathcal{W}_{\text{side}}, \mathcal{W}_{\text{cross}}, \) and \( \mathcal{O}_{\text{slack}} \) can be precomputed offline for given road networks.

### C. Constraint Management

The prediction of each pedestrian is based on traffic rules, which are represented by the constraints introduced in Tab. I. The Boolean variables are initialized with \( b = \text{true} \) and then set according to the conditions listed in the last column of Tab. I. Thus, constraints are automatically deactivated as soon as assumptions on the traffic rules are violated. Let us explain the constraint management for \( C_{\text{stop}} \) and \( C_{\text{perp}} \) in more detail. For \( C_{\text{stop}} \), pedestrians are anticipated to step on the roadway if they cannot stop before; in this case, \( b_{\text{stop}} = \text{false} \). The condition of \( C_{\text{perp}} \) further anticipates that the pedestrian crosses the road if stopping within \( \mathcal{O}_{\text{stop}} \) is not possible or if \( \mathcal{W}_{\text{forbid}} \) is intruded by more than the maximum of \( \xi_{\text{slack}} \) and \( r_{\text{stop}} + r_{\text{ped}} \); in these cases, \( b_{\text{perp}} = \text{false} \).

Note that the proposed conditions for the constraints are deduced from traffic rules, but may be adapted to obtain more or less conservative behavior, e.g., a sophisticated intention prediction may directly set \( b_{\text{perp}} \) and \( b_{\text{slack}} \) to false (and increase \( \xi_{\text{perp}} \) and \( \xi_{\text{slack}} \)) for a child playing at the side of the road. Thus, our approach offers the possibility of deactivating constraints based on the specifications of users while still remaining formally valid.

For the dynamic-based occupancy, the constraints (6b) and (6c) are not deactivated if we measure higher values; instead, their maximum allowed values are adjusted as presented in the last two rows of Tab. II, where the parameters \( \Delta_{\text{max}} \) and \( \Delta_{\text{slack}} \) are thresholds to anticipate that the measured values might be exceeded and thus, the updated maximum values will not be directly violated again.

### IV. Evaluation with Real-world Data

We evaluate our approach using recorded data with measurement noise obtained from a moving vehicle [30]. Fig. 5 shows the view from the front camera of the autonomous vehicle and three tracked pedestrians crossing the street. The default values for the constraints in our prediction are listed in Tab. I. For the dynamic-based occupancy, the maximum acceleration and velocity must be parametrized. As in [23], we use as the default \( a_{\text{max}} = 0.6 \text{ m/s}^2 \) (based on a labeled video source [31]) and \( v_{\text{max}} = 2.0 \text{ m/s} \) (which
is the transition speed between walking and running and is suggested by [32]). One can also choose different values, e.g., from extensive physiological experiments on walking, running, and stopping [33]. Our results have been obtained using MATLAB 2016a on a machine with a 2.6 GHz Intel Core i7 processor with 20 GB 1600 MHz DDR3 memory.

A. Conformance of Dynamic-Based Occupancy

We validate our dynamic-based occupancy by checking whether our model over-approximates the real behavior of walking-only pedestrians, using $\Delta t = 0.1\, \text{s}$, $t_f - t_0 = 2.0\, \text{s}$, and $r_{\text{ped}} = 0.35\, \text{m}$. From [30], we predict 11 pedestrians for a total of 7008 $\text{s}$ with $\Delta_x \in [0.19\, \text{m}, 0.96\, \text{m}]$, $\Delta_y \in [0.21\, \text{m/s}, 1.5\, \text{m/s}]$, and $\Delta_v \in [0.21\, \text{rad}, 0.88\, \text{rad}]$. We achieve a coverage of 100%, since all recorded occupancies, i.e., ground-truth trajectories without uncertainty enlarged by $r_{\text{ped}}$, were fully contained within the predicted $O_{\text{dy}}(\tau_k)$. As an example, Fig. 6a depicts our result of the three pedestrians from Fig. 5. A snapshot in Fig. 6b for $\tau_0 = [0.9\, \text{s}, 1.0\, \text{s}]$ shows that our set-based prediction is not unreasonably conservative. Note that our prediction remains over-approximative for longer time horizons (tested for up to 5.0 $\text{s}$).

The computation time for each pedestrian was 23 ms; however, since the set intersection in (10) requires the most resources, the prediction only required 5 ms for $\Delta t = 0.5\, \text{s}$.

Furthermore, we also validated our model using ground truth trajectories of 389 pedestrians from the publicly available BIWI Walking Pedestrians dataset of a street scene in Zurich, Switzerland [31]. Again, we achieved 100% coverage using $\Delta_x \in [0.15\, \text{m}, 0.3\, \text{m}]$, $\Delta_y = 0.15\, \text{m/s}$, and $\Delta_v \in [0.2\, \text{rad}, 0.5\, \text{rad}]$.

B. Evaluation of Rule-Based Occupancy

Next, we demonstrate the influence of the constraints deduced from the traffic rules. As shown in Fig. 7a, the pedestrian just stepped onto the roadway (with $v_0 = 1.40\, \text{m/s}$ at $t_0 = 0\, \text{s}$). According to Tab. II, $b_{\text{slack}} = \text{false}$ and since $\exists t \in [t_0, t_f] : (O_{\text{dy}}(t) \cap O_{\text{stop}}(t)) \cap C(r_{\text{ped}}) = \emptyset$, $b_{\text{stop}} = \text{false}$. The resulting occupancy $(O_{\text{slack}} \cup O_{\text{stop}}) \cap O_{\text{dy}}(t)$ restricts the pedestrian from completely crossing the street. For $t_f - t_0 = 3.0\, \text{s}$, the computation time was 66 ms for $\Delta t = 0.1\, \text{s}$ and was reduced by a factor of 3 for $\Delta t = 0.5\, \text{s}$.

When the initial state is updated at $t_0 = 0.5\, \text{s}$, the pedestrian had made another step onto the roadway ($v_0 = 1.58\, \text{m/s}$, cf. Fig. 7b). Since the constraint management again detects that the occupancy is empty, $b_{\text{perp}} = \text{false}$ and we predict the pedestrian crossing the street perpendicular to the driving direction, as shown in Fig. 7b.

C. Application to Evasive Motion Planning

To demonstrate how the obtained prediction can be used for evasive trajectory planning of autonomous vehicles, we make use of a trajectory planner based on convex optimization techniques [3]. The scenarios presented next are available in the CommonRoad benchmark suite including all simulation parameters [34].

![Fig. 5. View from the front camera of the autonomous vehicle approaching three pedestrians crossing the street. The recorded data is provided by [30].](image1)

![Fig. 6. The predicted dynamic-based occupancy contains the recorded occupancy of the three pedestrians at the crossing of Fig. 5](image2)

![Fig. 7. The rule-based occupancy intersected with $O_{\text{dy}}(t)$ for different stages of a pedestrian crossing the roadway.](image3)
The ego vehicle in our first scenario (cf. Fig. 8) CommonRoad ID: S=ZAM_Intersect-1_S-1:2018a) is approaching the intersection with a velocity of 13.8 m/s, while the pedestrian approaches a forbidden crossing (without priority due to a red traffic light) with $v_0 = 1.35$ m/s. Similar to the example in Sec. [V-B] the pedestrian cannot stop before entering the roadway and thus is predicted with $b_{\text{stop}} = \text{false}$. We plan an evasive maneuver which involves swerving to the left adjacent lane to avoid a collision. The obtained evasive trajectory is guaranteed to be collision-free given our assumptions (cf. Fig. 8).

Furthermore, the prediction can be used to proactively evaluate evasive options so that the number of available evasive maneuvers is increased. As an example, we consider the situation 0.5 s later when the pedestrian has already entered the forbidden crossing ($v_0 = 1.40$ m/s), implying $b_{\text{proo}} = \text{false}$ (cf. prediction in Fig. 8) CommonRoad ID: S=ZAM_Intersect-1_2_S-1:2018a). Considering the current velocity of the ego vehicle, a collision with the crossing pedestrian can only be avoided by swerving to the left adjacent lane (similar to the maneuver of the previous scenario, cf. Fig. 8). However, this may not be an option in the presence of other vehicles. Thus, we simultaneously plan evasive trajectories for different velocities of the vehicle. As a result, we observe that the ego vehicle is still able to avoid a collision using emergency braking for a velocity of 12.5 m/s (cf. trajectory in Fig. 9).

V. CONCLUSIONS

This paper proposes a formal prediction of the possible and legal future motion of pedestrians in an over-approximative, set-based fashion. By considering contextual information and the traffic rules pedestrians should adhere to, the prediction is significantly improved compared to a solely dynamical model. Nevertheless, our approach anticipates that pedestrians disregard rules and automatically adapts the prediction to ignore violated rules. We have validated our method using recorded motions of pedestrians and highlighted its use for evasive maneuver planning.

Future work includes further studies on pedestrian behavior to validate and parameterize the constraints based on the traffic rules. Furthermore, we are currently preparing real-world vehicle experiments for evasive maneuver planning considering pedestrians crossing the road.
