## Abstract

The concurrency relation of a Petri net contains the pairs of transitions that can be concurrently enabled. We present a polynomial algorithm to compute the concurrency relation of free-choice Signal Transition Graphs, a class of Petri nets with applications to the verification and synthesis of speed-independent circuits.

## 1 Introduction

Signal Transition Graphs (STGs) have become a popular and much studied formalism for the specification and verification of speed independent circuits [3, 8, 9]. STGs are 1-bounded Petri nets whose transitions carry labels of the form  $y^+$ ,  $y^-$ , where  $y$  is a circuit signal.<sup>1</sup> The occurrence of a transition with label  $y^+$  *raises*  $y$ , i.e., sets its value to 1, while the occurrence of a transition with label  $y^-$  *lowers*  $y$ , i.e., sets its value to 0.

A speed-independent circuit should never reach a state in which one circuit element wishes to lower the signal while another independently wishes to raise it, because then the behaviour of the circuit depends on the timing characteristics of the elements involved [12]. In an STG model this situation corresponds to the existence of a reachable marking which concurrently enables two transitions with opposite labels like  $y^+$  and  $y^-$ . Only STGs avoiding this situation can be implemented.

Another necessary condition for an STG to be implementable is the Complete State Coding property or the more restrictive Unique State Coding property [3]<sup>2</sup>. Pastor and Cortadella have recently described a procedure to verify if a free-choice STG satisfies the Unique State Coding property [10, 11] which requires to compute the concurrency relation, i.e., the pairs of transitions that can be concurrently enabled.

---

\*This work was Partially supported by the Sonderforschungsbereich 342 of the Deutsche Forschungsgemeinschaft, Teilprojekt A3.

<sup>1</sup>Originally, Chu defined STGs as free-choice Petri nets [3]. So Chu's STGs are what we call free-choice STGs in this paper.

<sup>2</sup>The precise definition of this property is not important for this paper.

The discussion of [12] and the result of [10] show that the concurrency relation of STGs has important applications. In this paper we present an algorithm which computes the concurrency relation for live and bounded free-choice nets, and therefore for live free-choice STGs, in  $O(n^3)$  time, where  $n$  is the number of places and transitions of the net. The restriction to live STGs is not significant, because non-live STGs are considered incorrect models, and liveness of free-choice STGs can be efficiently decided (see, for instance, [4, 7]). The algorithm is obtained following the lines of [6]. After some basic definitions (Section 2), we define the structural concurrency relation of a Petri net (Section 3). Then we prove that the concurrency and the structural concurrency relation coincide for live and bounded free-choice Petri nets (Section 4). Finally, we show that the structural concurrency relation can be computed in  $O(n^3)$  time, improving the algorithm given in [6], whose time complexity was  $O(n^5)$  (Section 5).

## 2 Basic definitions

A *net*  $N$  is a triple  $(S, T, F)$ , where  $S$  and  $T$  are two disjoint, finite sets of *places* and *transitions*, and  $F \subseteq (S \times T) \cup (T \times S)$  is a *flow relation*. Places and transitions are generically called *nodes*. We identify  $F$  with its characteristic function  $(S \times T) \cup (T \times S) \rightarrow \{0, 1\}$ .

Given a node  $x$  of  $N$ ,  $\bullet x = \{y \mid (y, x) \in F\}$  is the *preset* of  $x$  and  $x^\bullet = \{y \mid (x, y) \in F\}$  is the *postset* of  $x$ . Given a set of nodes  $X$  of  $N$ , we define  $\bullet X = \bigcup_{x \in X} \bullet x$  and  $X^\bullet = \bigcup_{x \in X} x^\bullet$ .

A triple  $(S', T', F')$  is a *subnet* of  $N$  if  $S' \subseteq S$ ,  $T' \subseteq T$  and  $F' = F \cap ((S' \times T') \cup (T' \times S'))$ . If  $X$  is a set of elements of  $N$ , then the triple  $(S \cap X, T \cap X, F \cap (X \times X))$  is a subnet of  $N$ , called the subnet of  $N$  *generated by*  $X$ .

A net  $(S, T, F)$  is a *T-net* if  $|\bullet s| = 1 = |s^\bullet|$  for every place  $s$ . It is a *free-choice net* if  $(s, t) \in F$  implies  $\bullet t \times s^\bullet \subseteq F$  for every place  $s$ .<sup>3</sup>

A *labelled net*  $N$  is a fourtuple  $(S, T, W, l)$ , where  $(S, T, F)$  is a net, and  $l$  is a mapping  $T \rightarrow Act$ , where  $Act$  is a set of actions. A *marking* of  $N$  is a mapping  $M: S \rightarrow \mathbb{N}$ . A marking  $M$  *enables* a transition  $t$  if  $M(s) \geq F(s, t)$  for every place  $s$ . If  $t$  is enabled at  $M$ , then it can *occur*, and its occurrence leads to the successor marking  $M'$  which is defined for every place  $s$  by

$$M'(s) = M(s) + \sum_{t \in T} F(t, s) - F(s, t)$$

A *Petri net* or *net system* is a pair  $\Sigma = (N, M_0)$  where  $N$  is a connected net and  $M_0$  is a marking of  $N$ . The connectedness of  $N$  is not a constraint, because the concurrency relation of a net system can be easily obtained from the concurrency relations of its connected components. The expression  $M_1 \xrightarrow{t} M_2$ , where  $M_1, M_2$  are markings of  $N$ , denotes that  $M_1$  enables transition  $t$ , and that the marking reached by the occurrence of  $t$  is  $M_2$ . The empty sequence  $\epsilon$  is an occurrence sequence: we have  $M \xrightarrow{\epsilon} M$  for every marking  $M$ .

A *T-system* (*free-choice system*, *labelled system*) is a pair  $\Sigma = (N, M_0)$  where  $N$  is a T-net (free-choice net, labelled net) and  $M_0$  is a marking of  $N$ .

A net system is *live* if for every reachable marking  $M$  and every transition  $t$  there exists a marking  $M'$  reachable from  $M$  which enables  $t$ . If  $(N, M_0)$  is a live system, then we also say that  $M_0$  is a *live marking* of  $N$ .

---

<sup>3</sup>We follow the terminology of [4]. These nets are also called extended free-choice nets in the literature.

A net system is *b-bounded* if  $M(s) \leq b$  for every place  $s$  and every reachable marking  $M$ . A net system is *bounded* if it is *b-bounded* for some number  $b$ . If  $(N, M_0)$  is a bounded system, we also say that  $M_0$  is a bounded marking of  $N$ .

### 3 Concurrency relations

The concurrency relation is usually defined as a set of pairs of transitions. We use a more general definition.

Let  $(N, M_0)$  be a net system, and let  $X$  be the set of nodes of  $N$ . Given  $x \in X$ , define the marking  $M_x$  of  $N$  as follows:

- if  $x$  is a place, then  $M_x$  is the marking that puts one token on  $s$ , and no tokens elsewhere;
- if  $x$  is a transition, then  $M_x$  is the marking that puts one token on every input place of  $x$ , and no tokens elsewhere.

The *concurrency relation*  $\parallel \subseteq X \times X$  contains the pairs  $(x_1, x_2)$  such that  $M \geq M_{x_1} + M_{x_2}$  for some reachable marking  $M$ . In particular, two transitions  $t_1, t_2$  belong to the concurrency relation if they can occur concurrently from some reachable marking, and two places belong to the concurrency relation if they are simultaneously marked at some reachable marking.

The concurrency relation is very related to the *co* relation used in the theory of nonsequential processes [1]:  $(x_1, x_2)$  belongs to the concurrency relation if and only if some nonsequential process of  $(N, M_0)$  contains two elements in *co* labelled by  $x_1$  and  $x_2$ . This is in fact a more elegant definition, but, since it requires to introduce a number of concepts, we use the one above.

We now define the structural concurrency relation, first presented in [6]:

**Definition 3.1**    *Structural concurrency relation*

Let  $(N, M_0)$  be a system, where  $N = (S, T, F)$ , and let  $X = S \cup T$ . The *structural concurrency relation*  $\parallel^A \subseteq X \times X$  is the smallest symmetric relation such that:

- (i)  $\forall s, s' \in S: M_0 \geq M_s + M_{s'} \Rightarrow (s, s') \in \parallel^A$
- (ii)  $\forall t \in T: (\bullet t \times \bullet t) \setminus id_T \subseteq \parallel^A \Rightarrow (t \bullet \times t \bullet) \setminus id_T \subseteq \parallel^A$
- (iii)  $\forall x \in X \forall t \in T: \{x\} \times \bullet t \subseteq \parallel^A \Rightarrow (x, t) \in \parallel^A \wedge \{x\} \times t \bullet \subseteq \parallel^A$

where  $id_T$  denotes the identity relation on  $T$ .

Loosely speaking, condition (i) states that any two places marked at the initial marking are structurally concurrent (actually, this is the case for a pair  $(s, s)$  only if  $M_0$  puts at least two tokens on  $s$ ). Condition (ii) states that if all the input places of a transition are structurally concurrent, then so are its output places. Clearly, these two conditions are fulfilled by the concurrency relation  $\parallel$ . At first sight it could seem that  $\parallel$  also fulfills condition (iii), but this is not the case. This condition states that if a node is structurally concurrent with all the input places of a transition, then it is also structurally concurrent with all its output places.

**Fig. 1** A system for which  $\parallel \neq \parallel^A$

Figure 1 shows a system in which  $\parallel$  does not satisfy (iii):  $(s, s_1)$  and  $(s, s_2)$  are concurrent, because there are two *different* reachable markings which mark  $s, s_1$  and  $s, s_2$ , respectively, but there is no reachable marking which puts tokens simultaneously on  $s, s_1$  and  $s_2$ . So for this system we have  $\parallel \neq \parallel^A$ . Another example in which the system is live and 1-bounded can be found in [6].

The following results are proven in [6]:

**Theorem 3.2**

- (i) For every net system,  $\parallel \subseteq \parallel^A$ .
- (ii) For live T-systems,  $\parallel = \parallel^A$ .

■

## 4 The main result

We prove in this section that  $\parallel^A$  and  $\parallel$  coincide for live and bounded free-choice systems (and therefore for live free-choice STGs). The reader which is not interested in the details of the proof can safely jump to the next section.

The proof has much in common with the proof of the Second Confluence Theorem [4], which we now recall.

### 4.1 The Second Confluence Theorem

All the definitions and results of this subsection are taken from [4]. The Second Confluence Theorem states that if two live and bounded markings  $M_1$  and  $M_2$  of a free-choice net agree on all S-invariants, then they have a common successor, i.e., there exists a marking that is reachable from both  $M_1$  and  $M_2$ . Since it can be easily shown that any two reachable markings agree on all S-invariants, it follows that any two reachable markings have a common

successor. The result can be generalised to a set  $M_1, \dots, M_n$  of markings which agree pairwise on all invariants, and in the sequel we consider this more general version.

Let us first recall the notions of S-invariant and markings that agree on all S-invariants.

**Definition 4.1**

An S-invariant of a net  $N$  is a rational-valued solution of the equation  $X \cdot \mathbf{N} = \mathbf{0}$ .

Two markings  $M$  and  $M'$  of  $N$  agree on all S-invariants if  $I \cdot M = I \cdot M'$  for every S-invariant  $I$  of  $N$ .

**Theorem 4.2**

Let  $(N, M_0)$  be a system, and let  $M$  be a reachable marking. Then  $M$  and  $M_0$  agree on all S-invariants. ■

The proof of the Second Confluence Theorem distinguishes two cases, according to whether the free-choice net  $N$  is a T-net or not. The first case is easily solved using the following result, which states that for T-systems the converse of Theorem 4.2 holds:

**Theorem 4.3** *Reachability Theorem for T-systems*

Let  $(N, M_0)$  be a live T-system. A marking  $M$  is reachable iff it agrees with  $M_0$  on all S-invariants. ■

Since  $M_1, \dots, M_n$  are live and bounded and agree on all S-invariants, they are all reachable from each other. Therefore, any of them is a common successor of all the others.

In the second case, when  $N$  is not a T-net, the proof makes use of a reduction procedure.  $N$  is split into two: a subnet  $\widehat{N} = (\widehat{S}, \widehat{T}, \widehat{F})$  called CP-subnet in [4], and the subnet generated by all the nodes that do not belong to  $\widehat{N}$ , denoted by  $N \setminus \widehat{N}$ .

**Definition 4.4** *CP-subnets*

A subnet  $N' = (S', T', F')$  of a net  $N$  is a CP-subnet if it is

- (i) nonempty and weakly connected,
- (ii) transition-bordered (i.e., contains pre- and post-sets of all its places),
- (iii) a T-net (i.e., every place has exactly one input transition and one output transition),  
and
- (iv) the net  $N \setminus N'$  is strongly connected and contains some transition.

A transition  $t \in T'$  such that  $\bullet t \not\subseteq S'$  is called a *way-in* transition.

The following result guarantees that  $N$  can be split:

**Proposition 4.5**

A well-formed free-choice net is either a T-net or has a CP-subnet. ■

Once  $N$  is split, we let  $n$  particular sequences occur from  $M_1, \dots, M_n$ . These sequences contain only transitions of  $\widehat{N}$  which are not way-in transitions.

**Proposition 4.6** *Fundamental property of CP-subnets*

Let  $N$  be a well-formed free-choice net, and let  $M_1, \dots, M_n$  be live and bounded markings of  $N$  that agree on all S-invariants. Let  $\widehat{N}$  be a CP-subnet of  $N$ , let  $\widehat{T}_i$  be the set of way-in transitions of  $\widehat{N}$ , and let  $\overline{N} = N \setminus \widehat{N}$ . There exist occurrence sequences  $M_1 \xrightarrow{\sigma_1} M'_1, \dots, M_n \xrightarrow{\sigma_n} M'_n$ , where  $\sigma_1, \dots, \sigma_n$  contain only transitions of  $\widehat{T} \setminus \widehat{T}_{in}$ , such that

- (1) No transition of  $\widehat{T} \setminus \widehat{T}_{in}$  is enabled at  $M'_1, \dots, M'_n$ ,
- (2)  $\widehat{M}'_1 = \dots = \widehat{M}'_n$ , where  $\widehat{M}$  denotes the projection of  $M$  onto the places of  $\widehat{N}$ ,
- (3)  $\overline{M}_i \leq \overline{M}'_i$  for  $1 \leq i \leq n$ , where  $\overline{M}$  denotes the projection of  $M$  onto the places of  $\overline{N}$ ,  
and
- (4)  $\overline{M}'_1, \dots, \overline{M}'_n$  are live and bounded markings which agree on all S-invariants of  $\overline{N}$ .

■

After the occurrence of these sequences we ‘freeze’ the transitions of the CP-subnet, i.e., we forbid them to occur again, and preserve so the equality  $\widehat{M}'_1 = \dots = \widehat{M}'_n$ . If  $\overline{N}$  is a T-net, then Theorem 4.3 can be applied, and we are done. Otherwise, by Proposition 4.5 and Proposition 4.6(3) we can iterate the procedure until we get two markings which coincide everywhere, and are therefore the same. This marking is a common successor of  $M_1, \dots, M_n$ . Instead of freezing the transitions of the CP-subnet, we can equivalently remove it and consider thereafter the remaining net  $\overline{N}$ .

## 4.2 The new result

In order to adapt these results to the concurrency problem for free-choice systems, we have a closer look at the proof of Proposition 4.5, which shows how to construct a CP-subnet of a live and bounded free-choice system which is not a T-system. The proof is based on the notion of T-component.

**Definition 4.7** *T-components, T-covers*

Let  $N'$  be the subnet of a net  $N$  generated by a nonempty set  $X$  of nodes.  $N'$  is a T-component of  $N$  if:

- $\bullet t \cup t \bullet \subseteq X$  for every transition  $t$  of  $X$ , and
- $N'$  is a strongly connected T-net.

Let  $\mathcal{C}$  be a set of T-components of  $N$ .  $\mathcal{C}$  is a *T-cover* if every transition of  $N$  belongs to a T-component of  $\mathcal{C}$ . A net is covered by T-components if it has a T-cover.

It is easy to see that every node of the net, and not only every transition, belongs to some element of a T-cover.

We have the following well-known result:

**Theorem 4.8** *T-coverability Theorem*

Well-formed free-choice nets are covered by T-components. ■

Now, in order to find a CP-subnet, we proceed as follows. We take a minimal T-cover  $\mathcal{C}$  of  $N$ , i.e., no proper subset of  $\mathcal{C}$  is a cover. Since  $N$  is not a T-net, we have  $|\mathcal{C}| > 1$ . We construct the (non-directed) graph  $G = (V, E)$  as follows.

$$\begin{aligned} V &= \mathcal{C} \\ E &= \{(N_i, N_j) \mid N_i \text{ and } N_j \text{ have at least one common node}\} \end{aligned}$$

The graph  $G$  is connected because  $\mathcal{C}$  is a cover of  $N$  and  $N$  is connected. Moreover,  $G$  has at least two vertices because  $|\mathcal{C}| > 1$ .

We choose an spanning tree<sup>4</sup> of  $G$ , and select one of its leaves, say  $N_1$ . We then construct a maximal set of nodes  $X$  of  $N_1$  satisfying the following properties:

- (a) The net generated by  $X$  is connected, and
- (b) No element of  $X$  belongs to a T-component of  $\mathcal{C} \setminus \{N_1\}$ .

The set  $X$  is nonempty, because  $\mathcal{C}$  is a minimal cover. The subnet  $N_X$  generated by  $X$  is a CP-subnet.

We call the subnets  $N_X$  *private* subnets, because they are generated by nodes that  $N_1$  does not share with any other T-component of  $\mathcal{C}$ . So we have that private subnets are CP-subnets. Notice that a T-component may have more than one private subnet. However, if this is the case then the private subnets are disjoint (by the maximality condition on  $X$ ).

We are now ready to prove the following result.

**Proposition 4.9**

Let  $(N, M_0)$  be a live and bounded free-choice system, and let  $s$  and  $t$  be a place and a transition of  $N$  such that  $\bullet t = \{r_1, \dots, r_n\}$ . Assume that for every  $1 \leq i \leq n$  there exists a reachable marking  $M_i$  such that  $M_i \geq M_s + M_{r_i}$ . Then there exists a reachable marking  $M \geq M_s + \sum_{i=1}^n M_{r_i}$ .

**Proof:**

Let  $\mathcal{C}$  be a minimal T-cover of  $N$ , which exists by the T-coverability Theorem. We consider two cases:

- (a) Some T-component  $N_1$  of  $\mathcal{C}$  contains both  $s$  and  $t$ .

Let  $G$  be the graph described above, and let  $G_s$  be a spanning tree of  $G$ . We construct systems  $(N_1, M_1^f), \dots, (N_1, M_n^f)$  as follows. If  $G_s$  has only one node, then  $N = N_1$ , and we take  $(N_1, M_i^f) = (N_0, M_i)$ . If  $G_s$  has more than one node, we select one of its leaves, different from  $N_1$  (this is possible, because a spanning tree with at least two nodes has at least two leaves, and so we are never forced to select  $N_1$ ). Once such a

---

<sup>4</sup>A spanning tree is a cycle-free connected graph  $(V, E')$ ; it can be obtained from  $G$  by successive deletion of edges that belong to a cycle.

leaf  $N_i$  is chosen, we consider its private subnets one by one. For each private subnet, we execute the occurrence sequences of Proposition 4.6 from the markings  $M_1, \dots, M_n$ . After that, we remove the private subnet. We proceed like this with all the private subnets of  $N_i$ . We thus obtain systems  $(N', M'_1), \dots, (N', M'_n)$ , where  $N'$  is minimally covered by  $\mathcal{C}' = \mathcal{C} \setminus \{N_i\}$ . Moreover, the graph  $G'$  corresponding to the minimal cover  $\mathcal{C}'$  is the graph obtained from  $G$  by removing the node  $N'$ , and the graph  $G'_s$  obtained from  $G_s$  by removing the vertex  $N'$  is a spanning tree of  $G'$ . If  $G'_s$  contains more than one node, we iterate the procedure, this time starting from  $(N', M'_1), \dots, (N', M'_n)$  and  $G'_s$ .

Since each iteration removes one node from  $G$ , the procedure terminates when the spanning tree contains only one node. Since  $N_1$  is never removed, this node is  $n_1$ . So the procedure outputs systems  $(N_1, M_1^f), \dots, (N_1, M_n^f)$ .

Let  $M_{11}, \dots, M_{1n}$  be the projection of  $M_1, \dots, M_n$  onto the places of  $N_1$ . Since Proposition 4.6(2) can be applied each time we remove a private subnet, we have:

- (i)  $M_i^f \geq M_{1i}$  for  $1 \leq i \leq n$ , and
- (ii)  $M_1^f, \dots, M_n^f$  agree on all the invariants of  $N_1$ .

By (i),  $M_i^f \geq M_s + M_{r_i}$ . the result follows from (ii) and Theorem 3.2(i).

- (b) No T-component of  $\mathcal{C}$  contains both  $s$  and  $t$ .

Let  $N_1$  be a T-component of  $\mathcal{C}$  containing  $s$ . We choose a spanning tree  $G_s$  of  $G$ , and proceed as in (a), iteratively selecting a leaf different from  $N_1$ . However, we no longer stop when the spanning tree contains a node, but as soon as  $t$  belongs to a private subnet  $\widehat{N}$  of some leaf. Notice that this eventually happens, because otherwise the reduction process could continue until only  $N_1$  remains, which contradicts the assumption that no T-component of  $\mathcal{C}$  contains both  $s$  and  $t$ .

Let  $N'$  be the net obtained after termination, and let  $M_1^f, \dots, M_n^f$  be the corresponding markings. Further, let  $M'_1, \dots, M'_n$  be the projection of  $M_1, \dots, M_n$  onto the places of  $N'$ . By Proposition 4.6(3),  $M_i^f \geq M'_i$ , and therefore  $M_i^f$  marks both  $s$  and  $r_i$ . Now, by Proposition 4.6, there exist occurrence sequences  $\sigma_1, \dots, \sigma_n$  enabled at  $M_1^f, \dots, M_n^f$ , which contain only transitions of  $\widehat{T} \setminus \widehat{T}_{in}$ , and lead to markings satisfying two conditions:

- (i) the projections of  $M_1^f, \dots, M_n^f$  onto the places of  $\widehat{N}$  coincide, and
- (ii) no transition of  $\widehat{T} \setminus \widehat{T}_{in}$  is enabled at  $M_1^f, \dots, M_n^f$ .

Since  $\widehat{N}$  is a T-net, (i) and (ii) can only hold if all of  $\sigma_1, \dots, \sigma_n$  contain the transition  $t$ . Since  $s$  remains marked along the execution of these sequences, some reachable marking marks simultaneously  $s$  and all the input places of  $t$ . ■

Proposition 4.9 leads to our main result:

**Theorem 4.10** *Concurrency Theorem for free-choice systems*

The relations  $\parallel$  and  $\parallel^A$  coincide for live and bounded free-choice systems.

**Proof:**

We have  $\parallel \subseteq \parallel^A$  by Theorem 3.2(i). We prove that the  $\parallel$  relation of a live and bounded free-choice system  $(N, M_0)$  satisfies the three conditions of Definition 3.1. Since  $\parallel^A$  is the smallest symmetric relation satisfying these conditions, we have  $\parallel^A \subseteq \parallel$ , which finishes the proof. Condition (i) follows easily from the definition of  $\parallel$ . Condition (ii) is a direct consequence of the liveness of  $(N, M_0)$ . Condition (iii) follows immediately from Proposition 4.9. ■

## 5 Computing the structural concurrency relation

In [6], the first author presented a  $O(n^5)$  algorithm for the computation of  $\parallel^A$  in an arbitrary net system, where  $n$  is the number of places and transitions of the net. In this paper we show that  $\parallel^A$  can be computed in  $O(n^4)$  time, and in  $O(n^3)$  time for free-choice systems.

**Algorithm 5.1**

**Input:** A live system  $(N, M_0)$ , where  $N = (S, T, F)$ .

**Output:**  $R \subseteq X \times X$ .

```

begin
   $R := \{(s, s') \mid M_0 \geq M_s + M_{s'}\} \cup \bigcup_{t \in T} t^\bullet \times t^\bullet$ ;
   $E := R \cap (X \times S)$ ;
  while  $E \neq \emptyset$  do
    choose  $(x, s) \in E$ ;  $E := E \setminus \{(x, s)\}$ ;
    for every  $t \in s^\bullet$  do
      if  $\{x\} \times t^\bullet \subseteq R$  then
         $E := E \cup ((\{x\} \times t^\bullet) \setminus R)$ ;
         $R := R \cup \{(x, t)\} \cup (\{x\} \times t^\bullet)$ 
      endif
    endfor
  endwhile
end

```

**Proposition 5.2**

Algorithm 5.1 terminates, and after termination  $R = \parallel^A$ .

**Proof:**

Observe that  $E \subseteq R$  is an invariant of the while loop and holds initially. Therefore, each execution of the while loop removes from  $E$  an element of  $E \cap R$ . This element is never added to  $E$  again. So the algorithm terminates.

Let  $Q$  be the value of  $R$  after termination. We prove:

(1)  $Q \subseteq \|\!^A$ .

We first prove that  $R \subseteq \|\!^A$  holds initially. We have  $\{(s, s') \mid M_0 \geq M_s + M_{s'}\} \subseteq \|\!^A$  by definition. Moreover, since  $(N, M_0)$  is live, for every transition  $t$  there is a reachable marking which simultaneously marks every output place of  $t$ . Therefore,  $\bigcup_{t \in T} t^\bullet \times t^\bullet \subseteq \|\!^A$ , and since  $\|\! \subseteq \|\!^A$ , we have  $\bigcup_{t \in T} t^\bullet \times t^\bullet \subseteq \|\!^A$ . So initially  $R \subseteq \|\!^A$ .

Moreover, it follows easily from the definition of  $\|\!^A$  that  $R \subseteq \|\!^A$  is an invariant of the while loop. So we have  $Q \subseteq \|\!^A$ .

(2)  $Q$  satisfies the three conditions of Definition 3.1.

Condition (i) and (ii) follow immediately from the initialisation of  $R$ . For condition (iii), let  $x \in X$  and  $t \in T$ . We have to prove:

$$\{x\} \times \bullet t \subseteq Q \implies (x, t) \in \|\!^A \wedge \{x\} \times t^\bullet \subseteq Q$$

If  $\{x\} \times \bullet t$  is not included in  $Q$ , we are done. So assume  $\{x\} \times \bullet t \subseteq Q$ .

Let  $(x, s)$  be the last element of  $\{x\} \times \bullet t$  which is removed from  $E$  during the execution of the algorithm. As we have seen above,  $(x, s)$  is never added to  $E$  again.

Assume that immediately after  $(x, s)$  is removed from  $E$ , we have  $(x, s') \notin R$  for some  $s' \in \bullet t$ . We prove that  $(x, s')$  is never added to  $R$  later on. Every new element added to  $R$  is also added to  $E$ , and every element of  $E$  is removed before termination. Therefore, if  $(x, s')$  were added to  $R$  it would later be removed from  $E$ , contradicting the definition of  $(x, s)$ .

Since  $\{x\} \times \bullet t \subseteq R$  and no element of  $\{x\} \times \bullet t$  is added to  $R$  after  $(x, s)$  is removed from  $E$ , we already have  $\{x\} \times \bullet t \subseteq R$  immediately after  $(x, s)$  is removed from  $E$ . Then, the next execution of the for loop adds  $(\{x\} \times t^\bullet)$  to  $Q$ . So  $(\{x\} \times t^\bullet) \subseteq Q$  after termination.

$Q = \|\!^A$  follows from (1), (2) and the minimality of  $\|\!^A$ . ■

We calculate the complexity of the algorithm when the subsets  $X \times X$  (in particular, the incidence relations of the net) are encoded as bidimensional arrays  $X \times X \rightarrow \{0, 1\}$ . In this case, the algorithm needs  $O(|X|^2)$  space, and the following operations take constant time for every  $(x, y) \in X \times X$  and  $R \subseteq X \times X$ :

- determine if  $x \in \bullet y$  ( $x \in y^\bullet$ );
- determine if  $(x, y) \in R$ ;
- add  $(x, y)$  to  $R$ ;

- remove  $(x, y)$  from  $R$ .

The initialisation of  $Q$ ,  $E$  and  $N$  takes  $O(|S|^2 \cdot |T|)$  time. The **while** loop is executed at most  $O(|S| \cdot |X|)$  times, because each iteration removes one element from  $E$  which is never added to it again. One iteration takes  $O(|S| \cdot |T|)$  time ( $O(|T|)$  iterations of the **for** loop requiring  $O(|S|)$  time each). So the algorithm runs in  $O(|S|^2 \cdot |T| \cdot |X|)$  time.

It is possible to give a faster algorithm for free-choice systems, because they satisfy the following property:  $\bullet t_1 = \bullet t_2$  for every two output transitions  $t_1, t_2$  of a place  $s$ . In this case, the condition of the if instruction in the algorithm above holds either for all or for none of the transitions  $t \in s^\bullet$ . So, instead of checking the condition for each transition of  $s^\bullet$ , we may just check it for one of them. If the condition holds, we may then immediately add to  $R$  the set  $\{x\} \times \bigcup_{t \in s^\bullet} t^\bullet = \{x\} \times (s^\bullet)^\bullet$ . If we precompute the set  $\{(s, s') \mid s' \in (s^\bullet)^\bullet\}$  in the initialisation step, which can be done in  $O(|S|^2 \times |T|)$ , this assignment requires only  $O(|S|)$  time.

We get the following algorithm:

### Algorithm 5.3

**Input:** A live free-choice system  $(N, M_0)$ , where  $N = (S, T, F)$ .  
**Output:**  $R \subseteq X \times X$ .

```

begin
   $R := \{(s, s') \mid M_0 \geq M_s + M_{s'}\} \cup \bigcup_{t \in T} t^\bullet \times t^\bullet$ ;
   $A := \{(s, s') \mid s' \in (s^\bullet)^\bullet\}$ ;
   $E := R \cap (X \times S)$ ;
  while  $E \neq \emptyset$  do
    choose  $(x, s) \in E$ ;  $E := E \setminus \{(x, s)\}$ ;
    choose  $t \in s^\bullet$ ;
    if  $\{x\} \times \bullet t \subseteq R$  then
       $E := E \cup \{(x, s') \mid (s, s') \in A\} \setminus R$ ;
       $R := R \cup \{(x, s') \mid (s, s') \in A\}$ 
    endif
  endwhile
end

```

An iteration of the while loop requires only  $O(|X|)$  time, and not  $O(|S| \cdot |T|)$ , as was the case in Algorithm 5.1. Since the initialisation step can still be executed in  $O(|S|^2 \times |T|)$ , Algorithm 5.3 runs in  $O(|S| \cdot |X|^2)$  time.

## 6 Conclusions

We have presented an  $O(n^3)$  algorithm for the computation of the concurrency relation of live and bounded free-choice systems, where  $n$  is the number of nodes of the net. Our work was motivated by the interesting applications of the concurrency relation to the design

and verification of asynchronous circuits. Our algorithm can be used to detect undesirable race conditions in free-choice Signal Transition Diagrams (STGs) modelling specifications of speed-independent circuits. It can also be used as subroutine in the algorithm for checking the Unique State Coding property presented in [10, 11].

Pastor and Cortadella give in [11] an  $O(n^3)$  algorithm for the computation of the concurrency relation. The algorithm is based on some plausible but so far unproved properties of free-choice systems. It also has some restrictions: it only works for 1-bounded free-choice STGs without linearly dependent places, in which the initial marking is a home marking (i.e., can be reached from any other reachable marking). We have managed to solve these problems: our algorithm has a formal proof, is simpler, more general, and has the same complexity.

Our paper adds one more to the list of results on the concurrency problem, i.e., the problem of deciding if two given transitions of a Petri net are concurrently enabled at some reachable marking. The problem is EXPSPACE-hard for arbitrary net systems, and PSPACE-complete for 1-bounded systems [2]. It has been shown to be polynomial for live T-systems [6], 1-bounded conflict-free systems [13, 5] (although the algorithm of [5] can be easily generalised to the  $n$ -bounded case), and now for live and bounded free-choice systems.

Our algorithm also can be used to solve the 1-boundedness problem: decide if a given live and bounded free-choice system is 1-bounded. It follows easily from the definition of the concurrency relation that a net system is 1-safe iff its concurrency relation is irreflexive. So the 1-boundedness problem can be solved in  $O(n^3)$  as well. This improves the complexity of earlier algorithms based on linear programming.

## Acknowledgements

Many thanks to Jordi Cortadella and Enric Pastor for helpful discussions, and for drawing our attention to the concurrency problem for STGs.
