Abstract

We present the results of the ARCH¹ 2022 friendly competition for formal verification of continuous and hybrid systems with linear continuous dynamics. In its sixth edition, two tools have been applied to solve nine different benchmark problems in the category for linear continuous dynamics (in alphabetical order): CORA and JuliaReach. This report is a snapshot of the current landscape of tools and the types of benchmarks they are particularly suited for. Due to the diversity of problems, we are not ranking tools, yet the presented results provide one of the most complete assessments of tools for the safety verification of continuous and hybrid systems with linear continuous dynamics up to this date.

1 Introduction

Disclaimer The presented report of the ARCH friendly competition for continuous and hybrid systems with linear continuous dynamics aims at providing a landscape of the current capabilities of verification tools. We would like to stress that each tool has unique strengths—not all of the specificities can be highlighted within a single report. To reach a consensus in what benchmarks are used, some compromises had to be made so that some tools may benefit more from the presented choice than others.

We consider the verification of hybrid systems (i.e., mixed discrete/continuous systems) with linear continuous dynamics

\[ \dot{x}(t) = Ax(t) + Bu(t), \]

¹Workshop on Applied Verification for Continuous and Hybrid Systems (ARCH), cps-vo.org/group/ARCH
where $A \in \mathbb{R}^{n \times n}$, $x \in \mathbb{R}^n$, $B \in \mathbb{R}^{n \times m}$, and $u \in \mathbb{R}^m$. For all results reported by each participant, we have run an independent repeatability evaluation. To establish further trustworthiness of the results, the code with which the results have been obtained is publicly available at gitlab.com/goranf/ARCH-COMP. The selection of the benchmarks has been conducted within the forum of the ARCH website (cps-vo.org/group/ARCH), which is visible for registered users and registration is open to anybody. All tools presented in this report use some form of reachability analysis. This, however, is not a constraint set by the organizers of the friendly competition. We hope to encourage further tool developers to showcase their results in future editions. All tools are run on a AWS g4dn.4xlarge machine with 16 Xeon vCPUs and 64 GB RAM. Although we use the same machine, one still has to factor in the efficiency of the programming language of the tools.

2 Participating Tools

The tools participating in the category Continuous and Hybrid Systems with Linear Continuous Dynamics are subsequently introduced in alphabetical order.

**CORA** (Matthias Althoff, Mark Wetzlinger) The tool COntinuous Reachability Analyzer (CORA) [2, 5, 6, 4] realizes techniques for reachability analysis with a special focus on developing scalable solutions for verifying hybrid systems with nonlinear continuous dynamics and/or nonlinear differential-algebraic equations. A further focus is on considering uncertain parameters and system inputs. Due to the modular design of CORA, much functionality can be used for other purposes that require resource-efficient representations of multi-dimensional sets and operations on them. CORA is implemented as an object-oriented MATLAB code. CORA is available at cora.in.tum.de.

**JuliaReach** (Marcelo Forets, Christian Schilling) JuliaReach is a software suite for reachability computations of dynamical systems [16], available at http://juliareach.com/. It is written in Julia, a modern high-level language for scientific computing. The core library is ReachabilityAnalysis.jl and for the set computations we use our LazySets.jl library [22]. JuliaReach can analyze systems in either continuous-time or discrete-time semantics. For some of the models we use our custom parser for SpaceEx model files, and otherwise we create the models in Julia. In this competition we use the following algorithms: BFFPSV18 (based on the support function on low-dimensional subspaces [15]), GLGM06 (based on zonotopes [27]), ASB07 (based on zonotopes for parametric systems [10]), and LGG09 (based on the support function [30]). These algorithms can be combined with different approximation models [23], such as forward and correction hull, adapted from [15] and [1], respectively. For hybrid systems with time-triggered transitions, we use the algorithm from [21].

3 Verification of Benchmarks

For the 2022 edition, we have decided to keep all benchmarks from our 2021 friendly competition [11].

**Special Features** We briefly list the special features of each benchmark:
• Heat 3D benchmark from [13]: This is a purely continuous benchmark resulting from a spatial discretization of a heat partial differential equation in three dimensions. The system can be scaled from a $5 \times 5 \times 5$ mesh (125 dimensions) to a $100 \times 100 \times 100$ mesh (one million dimensions), each variation being roughly an order of magnitude apart.

• Clamped beam benchmark from [31, Sec. 4.2]: This purely continuous benchmark models a spatially discretized beam clamped on one end and pulled on the other end yielding interesting oscillations. The system dimension ranges from 200 to 2000 depending on the number of nodes used for the discretization. A challenge of this benchmark is that it has very little damping.

• Space station benchmark from [35]: This is a purely continuous benchmark of medium size with 270 state variables and three inputs.

• Spacecraft rendezvous benchmark from [18]: This benchmark has hybrid dynamics and is a linearization of a benchmark in the other ARCH-COMP category Continuous and Hybrid Systems with Nonlinear Dynamics. Consequently, the reader can observe the difference in computation time and verification results between the linearized version and the original dynamics.

• Powertrain benchmark from [7, Sec. 6]: This is a hybrid system for which one can select the number of continuous state variables and the size of the initial set. Up to 51 continuous state variables are considered.

• Building benchmark from [35, No. 2]: A purely continuous linear system with a small number of continuous state variables; the benchmark does not only have safety properties, but also properties that should be violated to check whether the reachable sets contain certain states.

• Platooning benchmark from [14]: A rather small number of continuous state variables is considered, but one can arbitrarily switch between two discrete states: a normal operation mode and a communication-failure mode.

• Gearbox benchmark from [19]: This benchmark has the smallest number of continuous state variables, but the reachable set does not converge to a steady state and the reachable set for one point in time might intersect multiple guards at once.

• Brake benchmark from [34]: This hybrid benchmark has a time-triggered discrete transition that has to be taken 1,001 times.

Types of Inputs  Generally, we distinguish between three types of inputs:

1. Fixed inputs, where $u(t)$ is precisely known. In some cases, $u(t) = \text{const}$ as in the gearbox benchmark.

2. Uncertain but constant inputs, where $u(t) \in U \subseteq \mathbb{R}^m$ is uncertain within a set $U$, but each uncertain input is constant over time: $u(t) = \text{const}$.

3. Uncertain, time-varying inputs $u(t) \in U \subseteq \mathbb{R}^m$ where $u(t) \neq \text{const}$. Those systems do not converge to a steady state solution and consider uncertain inputs of all frequencies. For tools that cannot consider arbitrarily varying inputs, we have stated that changes in inputs are only considered at fixed points in time.
Different Paths to Success  When tools use a fundamentally different way of solving a benchmark problem, we add further explanations.

Computation Time  The computation times specified in this report include the computation time of the reachable set and the time needed for the verification of the specifications.

3.1  Heat3D

3.1.1  Model

Using a mesh, the Heat3D benchmark is a spatially-discretized partial differential equation (PDE) for heat transfer in three dimensions, resulting in ordinary differential equations (ODEs), where each variable represents a mesh point. Depending on the granularity of the discretization, one can adjust the number of variables. This system has no switching or inputs and serves to evaluate the scalability with respect to the number of system dimensions. It is an academic example, although modifications, such as external inputs or more complicated specifications, can be added in the future. This benchmark was used in [13] and is based on a 2D version originally described and evaluated in [29, 28].

All of the sides of the considered heated block are insulated, except the \( x = 1 \) edge, causing heat exchange with the ambient environment with a heat exchange constant of \( 0.5 \). A heated initial region is present in the region, where \( x \in [0.0, 0.4] \), \( y \in [0.0, 0.2] \), and \( z \in [0.0, 0.1] \). The entire initial heated region is the same temperature, which is nondeterministic and chosen in the range 0.9 to 1.1, with the remaining material initially at temperature 0.0. The system dynamics is given by the heat equation PDE \( u_t = \alpha^2 (u_{xx} + u_{yy} + u_{zz}) \), where \( \alpha = 0.01 \) is the diffusivity of the material.

A linear model of the system is obtained using the semi-finite difference method, discretizing the block with an \( m \times m \times m \) grid. This results in an \( m^3 \)-dimensional linear system describing the evolution of the temperature at each mesh point.

Due to the initially heated region, we expect the temperature at the center of the block to first increase, and then decrease due to the heat loss along the \( x = 1 \) edge. Further, the discretization error increases for smaller \( m \) motivating the higher-dimensional versions of the benchmark. We suggest a time bound of \( T = 40 \) and a step size of 0.02 (2000 steps).

3.1.2  Specifications

The goal is to find the maximum temperature reached at the center of a \( 1 \times 1 \times 1 \) block, where one edge of the block is initially heated. This can be converted to a safety verification problem by checking that \( T_{\text{max}} \) is reachable but \( T_{\text{max}} + \delta \) is not, for some small \( \delta \) like \( 10^{-4} \).

There are five suggested sizes, roughly each one an order of magnitude apart in terms of the number of dimensions. The higher-dimensional versions usually prevent explicitly representing the dynamics as a dense matrix in memory. Storing a million by million dense matrix requires a trillion numbers, which at 8 bytes per double-precision number would require eight terabytes of storage.

HEAT01  \( 5 \times 5 \times 5 \) (125 dimensions). Note: the initial set is modified to be heated when \( z \in [0.0, 0.2] \) (single mesh point), since that is the best we can do with this granularity. \( T_{\text{max}}: 0.10369 \) at time 9.44.

HEAT02  \( 10 \times 10 \times 10 \) (1000 dimensions). \( T_{\text{max}}: 0.02966 \) at time 25.5.
HEAT03 $20 \times 20 \times 20$ (8000 dimensions). $T_{\text{max}}$: 0.01716 at time 22.62.

HEAT04 $50 \times 50 \times 50$ (125,000 dimensions). $T_{\text{max}}$: 0.01161 at time 18.88.

HEAT05 $100 \times 100 \times 100$ (1,000,000 dimensions). $T_{\text{max}}$: 0.01005 at time 17.5.

### 3.1.3 Results

Plots for the $5 \times 5 \times 5$ case are shown in Figure 1. Results are shown in Table 1.

**Note CORA** CORA applies the reachability algorithm in [24] with a time step size of 0.02 for the benchmark instance HEAT01. For the higher-dimensional benchmark instances we compute the reachable set using the Krylov-subspace-based reachability algorithm in [3] using a time step size of 0.05 for HEAT02 and 0.005 for HEAT03.

**Note JuliaReach** We use the LGG09 algorithm. For HEAT03 and HEAT04 we lazily compute the matrix exponential using the Lanczos algorithm [32] with Krylov subspace dimension of 94 and 211, respectively.

Figure 1: Heat3D: Reachable sets for the temperature at the center of the block over time for benchmark version HEAT01. Some tools additionally show possible trajectories.

3.2 Clamped Beam

3.2.1 Model

Similarly to the Heat3D benchmark, the Clamped Beam benchmark \cite[Sec. 4.2]{31} also results from the spatial discretization of a partial differential equation (PDE), where each variable represents a node along the beam. The number of states scales proportionally with the number of nodes used for the discretization and the system is influenced by a single external input.

A beam of length $L$ is fixed at one end, while an external load $F(t)$ acts on the other end. Further model parameters are the cross-section area $A$ as well as the Young modulus $E$ and the density $\rho$ of the material. The governing PDE models the displacement $u(x,t)$ as a function of the position $x$ along the beam and the time $t$: $EAu_{xx} - \rho Au_{tt} = 0$. Here the indices indicate partial derivatives with respect to the indexed variables. To obtain a linear system, the beam is spatially discretized using $N$ nodes from $x = 0$ to $x = L$ depending on the stiffness matrix $K \in \mathbb{R}^{N \times N}$ and the mass matrix $M \in \mathbb{R}^{N \times N}$. The original model is extended by introducing a damping matrix $D = aK + bM$, where $a = b = 10^{-6}$, to model a more realistic beam. Rewriting the equation into a first-order system of linear ODEs yields a system dimension of $2N$ describing the displacement and velocity of each node over time. The sparsity pattern reveals four blocks of size $N \times N$: The block (1,1) is all-zero, the block (1,2) is the identity matrix, and the blocks (2,1) and (2,2) are tridiagonal matrices.

The initial condition is chosen such that all nodes have displacement and velocity zero, i.e., $\forall x \in [0, L]: u(x,0) = 0, u_t(x,0) = 0$. The boundary condition keeps the displacement at the fixed end zero at all times so that $\forall t: u(0,t) = 0$. The load is modeled by $F(t) = 10000H(t)$ with $H(t)$ denoting the Heaviside function. Finally, the time horizon is set to $T = 0.01$. For discrete-time tools, a step size of $9.88 \cdot 10^{-7}$ is used.

3.2.2 Specifications

The maximum velocity reached at the position $x = 0.7L$ should be below 76.

- CB01 $N = 100$ (200 dimensions).
- CB02 $N = 500$ (1000 dimensions).
- CB03 $N = 1000$ (2000 dimensions).

The load $F(t)$ is modeled in two different ways:

- CBC (constant inputs) The inputs are uncertain only in their initial value and constant over time: $F(0) \in \mathcal{F}$, $F(t) = 0$, with $\mathcal{F} = [9900, 10100]$.

- CBF (time-varying inputs) The inputs can change arbitrarily over time: $\forall t : F(t) \in \mathcal{F}$, with $\mathcal{F} = [9900, 10100]$.

Note that the load $F(t)$ of the original model is different from the input $u(t)$ to the spatially discretized system $\dot{x}(t) = Ax(t) + u(t)$.

3.2.3 Results

Plots for the velocity of the node at $x = 0.7L$, corresponding to node 70 are shown in Figure 2 over the time interval $t \in [0, 0.01]$. The computation times are shown in Table 2.
Note CORA  For CBC01, the CORA standard algorithm from [24] with a time step size of $1.429 \times 10^{-6}$ (7000 steps) was used, whereas for CBF01, we applied the wrapping-free algorithm from [26] with a time step size of $1.0 \times 10^{-6}$ (10000 steps). In both cases, the zonotope order was tuned to 25.

Note JuliaReach  We use LGG09 with step sizes $10^{-6}$ and $10^{-7}$ for CBC and CBF, respectively. For CBC we additionally use Krylov methods to efficiently compute the large matrix exponentials.

3.3 International Space Station Benchmark

3.3.1 Model

The International Space Station (ISS) is a continuous linear time-invariant system  $\dot{x}(t) = Ax(t) + Bu(t)$ proposed as a benchmark in ARCH 2016 [35]. In particular, the considered system is a structural model of the component 1R (Russian service module), which has 270 state variables with three inputs.

Initially, all 270 variables are in the range $[-0.0001, 0.0001]$, $u_1$ is in $[0, 0.1]$, $u_2$ is in $[0.8, 1]$, and $u_3$ is in $[0.9, 1]$. The time bound is 20. Discrete-time analysis for the space station benchmark should be done with a step size of 0.01. The A, B, and C matrices are available in MATLAB format\(^2\) (that can also be opened with Python using `scipy.io.loadmat`) and in SpaceEx format\(^3\). There are two versions of this benchmark:

ISSF01 The inputs can change arbitrarily over time: $\forall t : u(t) \in U$.

ISSC01 (constant inputs) The inputs are uncertain only in their initial value and constant over time: $u(0) \in U$, $\dot{u}(t) = 0$.

3.3.2 Specifications

The verification goal is to check the ranges reachable by the output $y_3$, which is a linear combination of the state variables ($y = Cx$, $C \in \mathbb{R}^{3 \times 270}$). In addition to the safety specification, for each version there is an UNSAT instance that serves as a sanity check to ensure that the model and the tool work as intended. But there is a caveat: In principle, verifying an UNSAT instance only makes sense formally if a witness is provided (counter-example, underapproximation, etc.). Since most of the participating tools do not have this capability, we run the tools with the same accuracy settings on an SAT-UNSAT pair of instances. The SAT instance demonstrates that the over-approximation is not too coarse, and the UNSAT instance demonstrates that the over-approximation is indeed conservative, at least in the narrow sense of the specification.

ISS01 Bounded time, safe property: For all $t \in [0, 20]$, $y_3(t) \in [-0.0007, 0.0007]$. This property is used with the uncertain input case (ISSF01) and assumed to be satisfied.

ISS02 Bounded time, safe property: For all $t \in [0, 20]$, $y_3(t) \in [-0.0005, 0.0005]$. This property is used with the constant input case (ISSC01) and assumed to be satisfied.

\(^2\) slicot.org/objects/software/shared/bench-data/iss.zip
\(^3\) cps-vo.org/node/34059

65
ISU01 Bounded time, unsafe property: For all \( t \in [0, 20] \), \( y_3(t) \in [-0.0005, 0.0005] \). This property is used with the uncertain input case (ISSF01) and assumed to be unsatisfied.

ISU02 Bounded time, unsafe property: For all \( t \in [0, 20] \), \( y_3(t) \in [-0.00017, 0.00017] \). This property is used with the constant input case (ISSC01) and assumed to be unsatisfied.

### 3.3.3 Results

Results of the international space station benchmark for state \( y_3 \) over time are shown in Fig. 4 and Fig. 5. The computation times of various tools for the benchmark are listed in Tab. 3.

**Note CORA** CORA applies the block-decomposition algorithm [17] with step size 0.01 and zonotope order 30 for benchmark version ISSF01. For version ISSC01, a step size of 0.02 and a zonotope order of 10 is used.

**Note JuliaReach** We use the LGG09 implementation. The step sizes in dense time are \( 6 \times 10^{-4} \) for ISSF01 and \( 1 \times 10^{-2} \) for ISSC01.

Table 3: Computation Times for the International Space Station Benchmark in [s].
3.4 Spacecraft Rendezvous Benchmark

3.4.1 Model

Spacecraft rendezvous is a perfect use case for formal verification of hybrid systems since mission failure can cost lives and is extremely expensive. This benchmark is taken from [18]; its original continuous dynamics is nonlinear, and the original system is verified in the ARCH-COMP category *Continuous and Hybrid Systems with Nonlinear Dynamics*. When spacecraft are in close proximity (such as rendezvous operations), a common approximation to analyze the nonlinear dynamics is to use the linearized Clohessy-Wiltshire-Hill (CWH) equations [20]. This benchmark analyzes this linear hybrid model.

The hybrid nature of this benchmark originates from a switched controller, while the dynamics of the spacecraft is purely continuous. In particular, the modes are approaching (100m-1000m), rendezvous attempt (less than 100m), and aborting. Discrete-time analysis for the rendezvous system should be done with a step size of 0.1. The model is available in C2E2, SDVTool, and SpaceEx format on the ARCH website\(^4\). The set of initial states is

\[
\mathcal{X}_0 = \begin{bmatrix} -900 \\ -400 \\ 0 \\ 0 \end{bmatrix} \oplus \begin{bmatrix} [\!-25, 25] \\ [\!-25, 25] \\ 0 \\ 0 \end{bmatrix}.
\]

The following benchmark instances are considered:

SRNA01 The spacecraft approaches the target as planned and there exists no transition into the aborting mode.

SRA01 A transition into aborting mode occurs at time \( t = 120 \) [min].

SRA02 A transition into aborting mode occurs nondeterministically, \( t \in [120, 125] \) [min].

SRA03 A transition into aborting mode occurs nondeterministically, \( t \in [120, 145] \) [min].

\(^4\) cps-vo.org/node/36349
A transition into *aborting* mode occurs at time $t = 240$ [min].

A transition into *aborting* mode occurs nondeterministically, $t \in [235, 240]$ [min].

A transition into *aborting* mode occurs nondeterministically, $t \in [230, 240]$ [min].

A transition into *aborting* mode occurs nondeterministically, $t \in [50, 150]$ [min].

A transition into *aborting* mode occurs nondeterministically, $t \in [0, 240]$ [min].

An initial, discrete-time analysis indicated it is safe to enter the *aborting* mode up to around time $t = 250$ [min]. We also added the following two instances, which are presumably unsafe. For timing, tools should use the same settings for these as for the safe cases.

A transition into *aborting* mode occurs at time $t = 260$ [min].

A transition into *aborting* mode occurs nondeterministically, $t \in [0, 260]$ [min].

### 3.4.2 Specifications

Given the thrust constraints of the specified model, in mode *rendezvous attempt*, the absolute velocity must stay below 0.055 m/s. In the *aborting* mode, the vehicle must avoid the target, which is modeled as a box $B$ with 0.2 m edge length and the center placed as the origin. In the *rendezvous attempt* the spacecraft must remain within the line-of-sight cone

$$L = \{ [x, y]^T | (x \geq -100 \text{ m}) \land (y \geq x \tan(30^\circ)) \land (-y \geq x \tan(30^\circ)) \}. $$

It is sufficient to check these parameters for a time horizon of 300 minutes.

Let us denote the discrete state by $z(t)$ and the continuous state vector by $x(t) = [s_x, s_y, v_x, v_y]^T$, where $s_x$ and $s_y$ are the positions in x- and y-direction, respectively, and $v_x$ and $v_y$ are the velocities in x- and y-direction, respectively. The mode *approaching* is denoted by $z_1$, the mode *rendezvous attempt* by $z_2$, and the mode *aborting* by $z_3$. We can formalize the specification as

$$\forall t \in [0, 300 \text{ min}], \forall x(0) \in X_0: (z(t) = z_2) \implies \left( \sqrt{v_x^2 + v_y^2} \leq 0.055 \text{ m/s} \land [s_x, s_y]^T \in L \right) \land (z(t) = z_3) \implies ([s_x, s_y]^T \notin B).$$

To solve the above specification, all tools under-approximate the nonlinear constraint $\sqrt{v_x^2 + v_y^2} \leq 0.055 \text{ m/s}$ by an octagon as shown in Fig. 6.

![Figure 6: Under-approximation of the nonlinear velocity constraint by an octagon.](image-url)
Remark on nonlinear constraint  In the original benchmark, the constraint on the velocity was set to 0.05 m/s, but it can be shown that this constraint cannot be satisfied by a counterexample. For this reason, we have relaxed the constraint to 0.055 m/s.

3.4.3 Results

Results of the spacecraft rendezvous benchmark for the $s_x$-$s_y$-plane are shown for the version SRNA01 in Fig. 7 and for the version SRA01 in Fig. 8. The computation times of various tools for the spacecraft rendezvous benchmark are listed in Tab. 4.

Note CORA  For both benchmark versions, CORA was run with a zonotope order of 10 and with the following step sizes: 0.2 [min] for the mode approaching, 0.02 [min] for the mode rendezvous attempt, and 0.2 [min] for the mode aborting (does not exist for version SRNA01). Intersections with deterministic guards are calculated with the method of Girard and Le Guernic in [25]. In order to find suitable orthogonal directions for the method in [25], we perform the following procedure: first, we project the last zonotope not intersecting the guard set onto the guard set; second, we apply principal component analysis to the generators of the projected zonotope, providing us with the orthogonal directions. For non-deterministic guards we first unite all reachable sets intersecting the guard set and then compute the intersection using constrained zonotopes [33].

Note JuliaReach  We use BFFPSV18 with a one-block partition and hyperrectangular reach sets with step size 0.04 (in dense time) for instances SRA01-SRA03. We handle discrete transitions by computing the intersection with invariants and guards lazily before their overapproximation with a hyperrectangle. For the instance SRA04, we use a clustering strategy of order 40 and step size 0.01. For the unsat instances we use the step size 0.04.

Figure 7: Reachable sets for the spacecraft rendezvous benchmark in the $s_x$-$s_y$-plane for the benchmark variant without maneuver abortion (SRNA01).
Figure 8: Reachable sets for the spacecraft rendezvous benchmark in the $s_x$-$s_y$-plane for the benchmark variant with maneuver abortion at $t = 120$ [min] (SRA01, over analysis time horizon of 300 [min]).

3.5 Powertrain with Backlash

3.5.1 Model

The powertrain benchmark is an extensible benchmark for hybrid systems with linear continuous dynamics taken from [7, Sec. 6] and [12, Sec. 4]. The essence of this benchmark is recalled here, and the reader is referred to the above-cited papers for more details. The benchmark considers the powertrain of a vehicle consisting of its motor and several rotating masses representing different components of the powertrain, e.g., gears, differential, and clutch, as illustrated in Fig. 9. The benchmark is extensible in the sense that the number of continuous states can be easily extended to $n = 7 + 2\theta$, where $\theta$ is the number of additional rotating masses. The number of discrete modes, however, is fixed and originates from backlash, which is caused by a physical gap between two components that are normally touching, such as gears. When the rotating components switch direction, for a short time they temporarily disconnect, and the system is said to be in the dead zone. The model is available in SpaceEx format on the ARCH website\(^5\).

\(^5\)cps-vo.org/node/49115
The set of initial states is

\[ X_0 = \{ c + \alpha g \mid \alpha \in [-1, 1] \} , \]

\[ c = [-0.0432, -11, 0, 30, 0, 30, 360, -0.0013, 30, \ldots, -0.0013, 30]^T , \]

\[ g = [0.0056, 4.67, 0, 10, 0, 10, 120, 0.0006, 10, \ldots, 0.0006, 10]^T . \]

Figure 9: Powertrain model.

### 3.5.2 Specifications

We analyze an extreme maneuver from a maximum negative acceleration that lasts for 0.2 [s], followed by a maximum positive acceleration that lasts for 1.8 [s]. The initial states of the model are on a line segment in the \( n \)-dimensional space. We create different difficulty levels of the reachability problem by scaling down the initial states by some percentage. The model has the following non-formal specification: after the change of direction of acceleration, the powertrain completely passes the dead zone before being able to transmit torque again. Due to oscillations in the torque transmission, the powertrain should not re-enter the dead zone of the backlash.

To formalize the specification using linear time logic (LTL), let us introduce the following discrete states:

- \( z_1 \): left contact zone
- \( z_2 \): dead zone
- \( z_3 \): right contact zone

For all instances, the common specification is: For all \( t \in [0, 2] \), \( x(0) \in X_0 \), \( (z_2 U z_3) \implies G(z_3) \). The instances only differ in the size of the system and the initial set, where \( \text{center}(\cdot) \) returns the volumetric center of a set.

\[ \text{DTN01 } \theta = 2, X_0 := 0.05(X_0 - \text{center}(X_0)) + \text{center}(X_0). \]

\[ \text{DTN02 } \theta = 2, X_0 := 0.3(X_0 - \text{center}(X_0)) + \text{center}(X_0). \]

\[ \text{DTN03 } \theta = 2, \text{no change of } X_0. \]
DTN04 $\theta = 22$, $X_0 := 0.05(X_0 - \text{center}(X_0)) + \text{center}(X_0)$.

DTN05 $\theta = 22$, $X_0 := 0.3(X_0 - \text{center}(X_0)) + \text{center}(X_0)$.

DTN06 $\theta = 22$, no change of $X_0$.

### 3.5.3 Results

Results of the powertrain benchmark in the $x_1$-$x_3$-plane are shown in Fig. 10. The computation times of various tools for the powertrain benchmark are listed in Tab. 5.

**Note CORA** CORA uses the following time step sizes: 0.005$s$ for DTN01, DTN02, and DTN03; 0.002$s$ for DTN04; and 0.001$s$ for DTN05 and DTN06. For all benchmark versions, CORA was run with a zonotope order of 20. The intersections with the guard sets are calculated with the approach from [25], and principal component analysis is used to find suitable directions for the enclosure of the guard intersections.

**Note JuliaReach** We use the GLGM06 algorithm with a step size of 0.001. In addition we use slightly different analysis parameters for different modes.

### 3.6 Building Benchmark

#### 3.6.1 Model

This benchmark is quite straightforward: The system is described by $\dot{x}(t) = Ax(t) + Bu(t)$, $u(t) \in U$, $y(t) = Cx(t)$, where $A$, $B$, $C$ are provided on the ARCH website\(^6\). The initial set and the uncertain input $U$ are provided in [35, Tab. 2.2]. Discrete-time analysis for the building system should use a step size of 0.01. There are two versions of this benchmark:

BLDF01 The inputs can change arbitrarily over time: $\forall t: u(t) \in U$.

BLDC01 (constant inputs) The inputs are uncertain only in their initial value, and constant over time: $u(0) \in U$, $\dot{u}(t) = 0$. The purpose of this model instance is to accommodate tools that cannot handle time-varying inputs.

#### 3.6.2 Specifications

The verification goal is to check whether the displacement $y_1$ of the top floor of the building remains below a given bound. In addition to the safety specification from the original benchmark, there are two UNSAT instances that serve as sanity checks to ensure that the model and the tool work as intended. But there is a caveat: In principle, verifying an UNSAT instance only

\(^6\)cps-vo.org/node/34059
Figure 10: Reachable sets in the $x_1$-$x_3$-plane.

makes sense formally if a witness is provided (counter-example, under-approximation, etc.). To make it possible to participate without this capability, we run the tools with the same accuracy settings on an SAT-UNSAT pair of instances. The SAT instance demonstrates that the over-approximation is not too coarse, and the UNSAT instance indicates that the over-approximation is indeed conservative.

**BDS01** Bounded time, safe property: For all $t \in [0, 20]$, $y_1(t) \leq 5.1 \cdot 10^{-3}$. This property is assumed to be satisfied.

**BDU01** Bounded time, unsafe property: For all $t \in [0, 20]$, $y_1(t) \leq 4 \cdot 10^{-3}$. This property is assumed to be violated. Property BDU01 serves as a sanity check. A tool should be run with the same accuracy settings on BLDF01-BDS01 and BLDF01-BDU01, returning UNSAT on the former and SAT on the latter.
BDU02 Bounded time, unsafe property: The forbidden states are \( \{ y_1(t) \leq -0.78 \cdot 10^{-3} \land t = 20 \} \). This property is assumed to be violated for BLDF01 and satisfied for BLDC01. Property BDU02 serves as a sanity check to confirm that time-varying inputs are taken into account. A tool should be run with the same accuracy settings on BLDF01-BDU02 and BLDC01-BDU02, returning UNSAT on the former and SAT on the latter.

3.6.3 Results

Results of the building benchmark for state \( x_{25} \) over time are shown in Fig. 11-14. The computation times of various tools for the building benchmark are listed in Tab. 6.

Note CORA Since the dynamics of this example is dominated by the input after one second, we use the step size 0.002 for \( t \in [0, 1] \) and the step size 0.01 for \( t \in [1, 20] \). The zonotope order is chosen as 100.

Note JuliaReach Since the safety property only involves one state variable, we use the LGG09 algorithm. Here we use the step sizes (in dense time) 0.004 for BLDF01 and 0.005 for BLDC01.

![Figure 11: Building (BLDF01): Reachable sets of \( x_{25} \) plotted over time up to time 1. Some tools additionally show possible trajectories.](image)

Table 6: Computation Times for the Building Benchmark in [s].
3.7 Platooning Benchmark

3.7.1 Model

The platooning benchmark considers a platoon of three vehicles following each other. This benchmark considers loss of communication between vehicles. The initial discrete state is $q_c$. Three scenarios are considered for the loss of communication:

PLAA01 (arbitrary loss) The loss of communication can occur at any time, see Fig. 15(a). This includes the possibility of no communication at all.
Figure 14: Building (BLDC01): Reachable sets of $x_{25}$ plotted over time up to time 20. Some tools additionally show possible trajectories.

**PLADxy** (loss at deterministic times) The loss of communication occurs at fixed points in time, which are determined by clock constraints $c_1$ and $c_2$ in Fig. 15(b). The clock $t$ is reset when communication is lost and when it is re-established. Note that the transitions have must-semantics, i.e., they take place as soon as possible.

**PLAD01:** $c_1 = c_2 = 5$.

**PLANxy** (loss at nondeterministic times) The loss of communication occurs at any time $t \in [t_b, t_c]$ in Fig. 15(c). The clock $t$ is reset when communication is lost and when it is re-established. Communication is reestablished at any time $t \in [0, t_r]$. This scenario covers loss of communication after an arbitrarily long time $t \geq t_c$ by reestablishing communication in zero time.

**PLAN01:** $t_b = 10, t_c = 20, t_r = 20$.

The models are available in SpaceEx, KeYmaera, and MATLAB/Simulink format on the ARCH website\(^7\). Discrete-time analysis for the platoon system should use a step size of 0.1.

**Discussion** The arbitrary-loss scenario (PLAA) subsumes the other two instances (PLAD, PLAN).

### 3.7.2 Specifications

The verification goal is to check whether the minimum distance between vehicles is preserved. The choice of the coordinate system is such that the minimum distance is a negative value.

**BNDxy** Bounded time (no explicit bound on the number of transitions): For all $t \in [0, 20]$ [s],

\[
x_1(t) \geq -d_{\text{min}} \text{[m]}, \quad x_4(t) \geq -d_{\text{min}} \text{[m]}, \quad \text{and} \quad x_7(t) \geq -d_{\text{min}} \text{[m]}.
\]

**BND50:** $d_{\text{min}} = 50$.

\(^7\)cps-vo.org/node/15096
\[ \dot{x} = A_c x + B_c a_L \quad x \in D_c \]

\[ \dot{x} = A_n x + B_n a_L \quad x \in D_n \]

(a) Arbitrary switching.

(b) Deterministic switching.

t = c_1

t := 0

t \in [t_b, t_c]

(c) Nondeterministic switching.

t = c_2

t := 0

t \in [0, t_r]

Figure 15: Three options adapted from the original benchmark proposal [14]. On the left, the system can switch arbitrarily between the modes. In the middle, mode switches are only possible at given points in time. On the right, mode switches are only possible during given time intervals.

\[ BND42: \quad d_{min} = 42. \]
\[ BND30: \quad d_{min} = 30. \]

UNBxy Unbounded time and unbounded switching: For all \( t \geq 0 \) [s], \( x_1(t) \geq -d_{min} \) [m], \( x_4(t) \geq -d_{min} \) [m], and \( x_7(t) \geq -d_{min} \) [m].

UNB50: \( d_{min} = 50. \)

UNB42: \( d_{min} = 42. \)

UNB30: \( d_{min} = 30. \)

3.7.3 Results

Results of the platoon benchmark for state \( x_1 \) over time are shown in Fig. 16-18. The computation times of various tools for the platoon benchmark are listed in Tab. 7.

Note CORA CORA was run with the following settings:

\begin{itemize}
  \item PLAA01-BND50: zonotope order 400 and time step size 0.02.
  \item PLAA01-BND42: zonotope order 800 and time step size 0.009.
  \item PLAD01-BND42: zonotope order 20 and time step size 0.02s.
  \item PLAD01-BND30: zonotope order 200 and time step size 0.02.
  \item PLAN01-UNB50: zonotope order 400 and time step size 0.01. To verify the specification for all times, the reachable set was increased by 1% at \( t = 50 \) and it was checked whether this set is re-entered.
  \item PLAA01: we used continuization [8, 9] to rewrite the hybrid automaton as a purely continuous system with uncertain parameters.
\end{itemize}

Note JuliaReach For PLAD01-BND42, we use the BFFPS18 algorithm with a one-block partition, hyperrectangular reach-sets, and a step size (in dense time) 0.01. For PLAD01-BND30, we use the LGG09 algorithm with a step size (in dense time) 0.03, and intersections with the guard are taken lazily with an octagonal template.
Figure 16: PLAA01: Reachable sets of $x_1$ plotted over time. CORA additionally shows possible trajectories.

Figure 17: PLAD01: Reachable sets of $x_1$ plotted over time. Some tools additionally show possible trajectories.

3.8 Gearbox Benchmark

3.8.1 Model

The gearbox benchmark models the motion of two meshing gears. When the gears collide, an elastic impact takes place. As soon as the gears are close enough, the gear is considered meshed. The model includes a monitor state that checks whether the gears are meshed or free and is available in SpaceEx format\textsuperscript{8} and as a Simulink model\textsuperscript{9}. Once the monitor reaches the state meshed, it stays there indefinitely.

With four continuous state variables, the gearbox benchmark has a relatively low number of continuous state variables. The challenging aspect of this benchmark is that the solution heavily depends on the initial state as already pointed out in [19]. For some initial continuous states, the target region is reached without any discrete transition, while for other initial states, several discrete transitions are required.

In the original benchmark, the position uncertainty in the direction of the velocity vector of the gear teeth (x-direction) is across the full width of the gear spline. Uncertainties of the position and velocity in y-direction, which is perpendicular to the x-direction, are considered to be smaller. Due to the sensitivity with respect to the initial set, we consider smaller initial sets. The full uncertainty in x-direction could be considered by splitting the uncertainty in x-direction and aggregating the individual results. For discrete-time analysis of the gearbox system, a step size of 0.0001 (1.0E-4) should be used.

GRBX01: The initial set is $x_0 = 0 \times 0 \times [-0.0168, -0.0166] \times [0.0029, 0.0031] \times 0$.

GRBX02: The initial set is $x_0 = 0 \times 0 \times [-0.01675, -0.01665] \times [0.00285, 0.00315] \times 0$.

\textsuperscript{8}cps-vo.org/node/34375
\textsuperscript{9}cps-vo.org/node/34374
3.8.2 Specification

The goal is to show that the gears are meshed within a time frame of $0.2 \text{ [s]}$ and that the bound $x_5 \leq 20 \text{ [Nm]}$ of the cumulated impulse is met. Using the monitor states free and meshed, and a global clock $t$, this can be expressed as a safety property as follows: For all $t \geq 0.2$, the monitor should be in meshed. Under nonblocking assumptions, this means that $t < 0.2$ whenever the monitor is not in meshed, i.e., when it is in free.

$\text{MES01: forbidden states: } (\text{free} \land t \geq 0.2) \lor (x_5 \geq 20)$

3.8.3 Results

Results of the benchmark for state $x_3$ and $x_4$ are shown in Fig. 19. The computation times of various tools for the benchmark are listed in Tab. 8.

Note CORA  CORA was run with a time step size of $0.0011$ and a zonotope order of 20. The intersections with the guard sets were calculated with the method of Girard and Le Guernic [25]. In order to find suitable orthogonal directions for the method in [25], we perform the following procedure: first, we project the last zonotope not intersecting the guard set onto the guard set; second, we apply principal component analysis to the generators of the projected zonotope, providing us with the orthogonal directions.

Note JuliaReach  We use the LGG09 algorithm with step sizes (in dense time) of $0.0005$ (GRBX01) resp. $0.0008$ (GRBX02).

![Figure 19: Gearbox (GRBX01): Reachable sets of $x_3$ and $x_4$.](image)

3.9 Brake Benchmark

3.9.1 Model

The brake benchmark models an electro-mechanical braking system, where a motor pushes a brake caliper against a brake disk that is connected to a (car) wheel [34]. The model describes a closed-loop system comprising a plant model as well as a controller and is representative for challenges in automotive systems. The original Simulink model has been simplified for usage in various analysis tools\(^{10}\). Here, we consider a linearized version with parameters.

\[
\begin{align*}
\dot{I} &= \frac{1}{L} \left( (K_P \cdot x_e + K_I \cdot x_c) - (R + \frac{K_P^2}{d_{rot}}) \cdot I \right) \\
\dot{x} &= \frac{K}{d_{rot}} \cdot I \\
\dot{x}_c &= 0 \\
\dot{T} &= 1 \\
T &\geq T_{sample} + \zeta \\
T' &= T - T_{sample} \\
x_c' &= x_0 - x \\
x_c' &= x_c + T_{sample} \cdot (x_0 - x) \\
T' &= T - T_{sample}
\end{align*}
\]

Figure 20: Hybrid automaton of the electro-mechanical brake with periodic discrete-time PI controller and sampling jitter.

The model is a hybrid automaton (see Fig. 20) with four state variables (the motor current \( I \), the brake position \( x \), and two auxiliary linearization variables) and a clock variable \( T \). The automaton consists of a single mode and a self-loop transition. The transition is time-triggered, i.e., it only depends on the value of the clock variable.

We consider two types of uncertainties in the model. The first uncertainty is a variation in the model parameters. We use the settings from [34] for the nonparametric and parametric scenarios. The second uncertainty is sampling jitter (i.e., nondeterministic switching). Unlike the linear model in [34], we consider jitter with a periodic clock (instead of a drifting clock).

\(^{10}\) cps-vo.org/node/20289
3.9.2 Specification

While structurally simple, the benchmark is challenging due to the large number of 1,001 discrete jumps within the time horizon 0.1. The initial state is the origin, we use the parameters \( x_0 = 0.05 \) and \( T_{\text{sample}} = 10^{-4} \), and in the case of nondeterministic switching the transitions are taken at multiples of \( T_{\text{sample}} \) with a nondeterministic jitter from the interval \( \zeta = [-10^{-8}, 10^{-7}] \). We study the property \( x < x_0 \) in both scenarios without and with parameter ranges:

BRKDC01: Verify that \( x < x_0 \) holds for the whole time horizon 0.1 (non-parametric scenario with deterministic switching).

BRKNC01: Same as BRKDC01, but with non-deterministic switching.

BRKNP01: Report the largest time horizon for which \( x < x_0 \) holds (parametric scenario with non-deterministic switching).

3.9.3 Results

Results of the benchmark are shown in Fig. 21. The computation times of various tools for the benchmark are listed in Tab. 9.

Note CORA  CORA was run with a time step size of \( 2^{-6} \), a zonotope order of 20, and the intersections with the non-deterministic guard sets were calculated with constrained zonotopes [33].

Note JuliaReach  For the BRKDC01 and BRKNC01 scenario, we use the GLGM06 algorithm with a fixed step size of \( 10^{-7} \) resp. \( 10^{-8} \). For the BRKNP01 scenario, we use the ASB07 algorithm with a step size of \( 10^{-8} \). In all scenarios we use the maximum zonotope order 1 (i.e., boxes). The discrete-time instances use the same step sizes as the dense-time instances. We use a custom analysis for dealing with the time-triggered transition efficiently, considering intersections with the guard separately from the flowpipe computation, as described in [21]. The largest time horizon for which \( x < x_0 \) holds for BRKNP01 is 0.0823s and 0.0824s for dense and discrete time, respectively.

4 Conclusion and Outlook

This report presents the results of the sixth friendly competition for the formal verification of continuous and hybrid systems with linear continuous dynamics as part of the ARCH’22 workshop. The reports of other categories can be found in the proceedings and on the ARCH website: cps-vo.org/group/ARCH.

A major observation of the results is that participating tools have significantly reduced computation times compared to the previous year. One can execute the dockerfiles of all tools on gitlab.com/goranf/ARCH-COMP using the command `measure_all`. Information about the competition in 2023 will be announced on the ARCH website.
