Abstract

Renal neuroendocrine tumors (RenNETs) are rare malignancies with largely unknown biology, hormone expression, and genetic abnormalities. This study aims to improve our understanding of the RenNETs with emphasis of functional, hormonal, and genetic features. Surgically resected RenNETs ($N=13$) were retrieved, and immunohistochemistry and next-generation sequencing (NGS) were performed in all cases. In addition, all published RenNETs were systematically reviewed. Our cohort (4 men and 9 women, mean age 42, mean tumor size 7.6 cm) included 2 patients with Cushing syndrome (CS). WHO grade (23% G1, 54% G2, and 23% G3) and tumor progression did not correlate. CS-associated RenNETs (CS-RenNETs) showed a solid and eosinophilic histology and stained for ACTH, while the remaining non-functioning tumors had a trabecular pattern and expressed variably hormones somatostatin (91%), pancreatic polypeptide (63%), glucagon (54%), and serotonin (18%). The transcription factors ISL1 and SATB2 were expressed in all non-functioning, but not in CS-RenNETs. NGS revealed no pathogenic alterations or gene fusions. In the literature review ($N=194$), 15 (8%) of the patients had hormonal syndromes, in which CS being the most frequent (7/15). Large tumor size and presence of metastasis were associated with shorter patients' survival ($p < 0.01$). RenNETs present as large tumors with metastases. CS-RenNETs differ through ACTH production and solid-eosinophilic histology from the non-functioning trabecular RenNETs that produce pancreas-related hormones and express ISL1 and SATB2. *MEN1* or *DAXX/ARTX* abnormalities and fusion genes are not detected in RenNETs, indicating a distinct yet unknown molecular pathogenesis.

Keywords Neuroendocrine neoplasms · Kidney · ISL1 · SATB2 · Hormone

Introduction

Well-differentiated neuroendocrine neoplasms (NETs) in genitourinary organs including renal NETs (RenNETs) are extremely rare compared to NETs occurring in digestive and thoracic organs [26]. About 200 RenNETs have been so far reported in the English literature, mostly as case reports or rare small series. RenNETs account for 0.18% (5/2780) of all primary renal neoplasms [37] and most arise in a normal kidney, but they may also occur in abnormal conditions, such as horseshoe kidney [20] and/or, rarely, within mature teratoma [30]. Regarding grading based on Ki67, no systematic evaluation of Ki67 has been performed to date in relation to patient outcome and metastatic potential in RenNETs [29].

The origin of RenNETs in the kidney is unclear since no neuroendocrine cells have so far been identified in normal renal tissue [57]. Apart from RenNETs, there are also poorly differentiated neuroendocrine neoplasms (carcinomas) in the kidney, most of them being small cell carcinomas and mixed non-neuroendocrine and endocrine neoplasms (MiNENs), mainly arising in the pelvis [38]. Few studies including altogether 16 RenNETs recorded the expression of hormones such as pancreatic polypeptide (PP), somatostatin, glucagon, or serotonin, but a systematic study on the hormonal profile in RenNETs is lacking [16, 22, 23, 32, 46, 53]. Transcription factors that are typical for the pancreas (islet 1, ISL1) [1], the lung (TTF1) [35], or the intestine (CDX2) [7] were examined in single case reports [12], while the expression of SATB2, a transcription factor characteristic for the lower digestive tract [13], has so far not been analyzed. Data on molecular genetic features of RenNETs are scarce and include one study based on NGS [44] and two studies focusing on loss of heterozygosity (LOH) on 3p [15, 34].

The discussion of the foregoing data shows that the available information on RenNETs is scarce. In particular, the prognostic assessment of RenNETs is poor compared to what is known in digestive tract NETs. Furthermore, it is unclear what biological relationship exists with pancreatic NETs (PanNET) and tumors with ACTH production. This study therefore focuses on four questions: (1) what is the prognostic significance of Ki67 index and WHO grade in RenNETs, (2) what is the incidence of functional syndromes in RenNETs, (3) are there histological and immunohistochemical features distinguishing non-functioning from Cushing syndrome associated RenNETs, and (4) are there molecular features that are unique to RenNETs?

Materials and methods

Tissue sampling and clinicopathological information

We identified surgically resected tumors diagnosed as primary renal neuroendocrine tumor or carcinoid over a period of 11 years (from 2011 to 2022) from the in-house surgical pathology files at the departments of pathology of the University Hospitals of Technical University Munich, University Hospital Düsseldorf, and University of Erlangen and also from the consultation files of two of the authors (AA and GK). NETs that had metastasized from other organs to the kidney were excluded in all cases by radiological and clinical findings. In all cases, formalin-fixed paraffin-embedded (FFPE) tissue blocks were available. The selected cases were reviewed and classified according to the WHO standards [48]. Nuclear Ki67 labeling was counted in more than 500 tumor cells in the area with the highest density (hot spot), and its percentage was reported as Ki67 index. Data on age, sex, tumor size and site, other renal diseases, hormonal symptoms, and presence or absence of metastasis were extracted from the available documents (see Table 1). This study was approved by the ethics committee of the Technical University Munich, Germany (approval number 2022–396-DFG-SR).

Histopathological and immunohistochemical evaluation

Immunohistochemical staining was performed on 2- μ m sections using an automated system (Benchmark XT; Ventana/Roche, AZ, USA). Details regarding the immunohistochemical stainings are given in Supplementary Table 1. The expression was regarded as diffuse when all tumor cells were strongly and evenly stained or patchy when the staining of the tumor cells alternates between weak and strongly and the weakly stained cells dominated. A single cell positivity (<5%) was regarded as negative. Membranous expression of the somatostatin receptor 2 (SST2) was evaluated based on the previously described method and a score 2+ and score 3+ were regarded as positive [42].

Molecular genetic studies

DNA and RNA, respectively, were each extracted from 5 slides with 8- μ m sections of FFPE materials that contain tumor tissue more than 50% of the section area. After proteinase k digestion, nucleic acids were extracted using a

semi-automated extraction system (Maxwell RSC 48, Promega, Madison, USA). Nucleic acid quantity was fluorometrically measured using the DNA high-sensitivity kit or the RNA high-sensitivity kit and the QuBit 4.0 instrument (Thermo Fisher Scientific, Waltham, USA). The amount of amplifiable DNA (sequencing grade quality) was determined using a commercially available qPCR assay (TaqMan RNase P detection assay) while RNA quality was determined by a custom-designed qPCR approach for amplification of the RNA of a housekeeping gene (HPRT) on a StepOnePlus instrument (Thermo Fisher Scientific). The DNA amount as input for library preparation was adjusted according to the amplifiability of the DNA and the grade of degradation. Hybrid capture and library preparation were conducted using the TruSight Oncology 500 assay (Illumina, San Diego, CA, USA), following the manufacturer's protocol. This assay allows targeted-capture sequencing of 523 cancer-related genes on the DNA level and translocation detection of 50 driver fusion genes on the RNA level. Up to eight DNA/RNA pairs were pooled together and sequenced on a NextSeq 550DX (Illumina) system using a NextSeq 500/550 High Output Kit v2.5 (300 Cycles). Data was processed and analyzed by the TruSight Oncology 500 Local App version 2.11.3, followed by an in-house pipeline using a second variant caller (Mutect2) and ANNOVAR for annotation of the alterations [11, 54]. For DNA analysis, single nucleotide variants, insertions/deletions, copy number variations, total mutation burden (TMB), and microsatellite instability (MSI) were calculated. For RNA analysis, putative gene fusion of around 50 fusion driver genes and RNA splice variants from EGFR, AR, or MET (e.g., MET exon 14 skipping) were explored. TMB was calculated by dividing the total number of somatic single nucleotide variants and insertions/deletions by the length of the captured coding region (~1.24 Mb). MSI quantitative score was calculated by interrogating 130 homopolymer MSI marker sites and defined as the proportion of MSI unstable sites to the total MSI sites. Variants were checked for germline or somatic origin using the COSMIC (catalog of somatic mutations in cancer) database [17], dbSNP, and the gnomAD database [25]. Interpretation of variants was performed using OncoKb, Varsome, and CKB [9, 31, 43].

Literature review and data collection

For a systematic review of RenNETs, we screened 204 articles written in English, Japanese, or German (14 articles in other languages reporting 18 cases were excluded) using the PubMed Keywords (renal[Title] AND (neuroendocrine tumor[Title])) OR (kidney[Title] AND (neuroendocrine tumor[Title])) OR (kidney[Title] AND (carcinoid[Title])) OR (renal[Title] AND (carcinoid[Title])). 61/204 articles dealing with non-renal NETs and 4 review articles were excluded. The remaining 139 articles

included 122 case reports and 17 series-based articles with a total of 227 cases. Data on sex, age, site, location, other renal disease, hormonal syndromes, outcome, Ki67 index, WHO grade, and immunohistochemical and genetic features were extracted. Outcome data such as progression-free survival (PFS) were defined as duration between the initial diagnosis and the first tumor progression, tumor-related death, or last observation. Outcome data were available in 120 cases with a mean follow-up duration of 33 months.

Statistical analyses

JMP Pro version 16.0.0 software (SAS Institute, Inc., Cary, NC, USA) was used for all statistical analyses. A correlation coefficient was calculated by Spearman's method. For the comparison among clinicopathological data extracted from the previously published patients' data, the sample number among multiple groups was compared using Pearson's chi-squared test or Fischer's exact test. The Wilcoxon test was applied for the comparisons of continuous values or scores between multiple groups found to be non-normally distributed by the Shapiro–Wilk test. The probability of differences in PFS was determined using the Kaplan–Meier method, with a log-rank test to test for significance. A *p* value of <0.05 was considered statistically significant.

Results

Patient characteristics and clinical features

Thirteen RenNETs were identified (5 in-house, 8 consultations). Table 1 summarizes the most important clinical data. The mean age of the patients was 42 years (range 27–63). Metastasis was detected in 67% (8/12, data missing in 1 case) of the patients at the time of the first diagnosis. 62% (8/13) of the tumors were found in the right kidney, 38% in the left. None of the tumors was associated with horseshoe kidney. Two patients (17%) presented with Cushing syndrome; the other 11 patients (83%) had no hormone-related syndromes. No patients have multiple endocrine neoplasm type 1 (MEN1) or other hereditary/genetic tumor syndromes. The non-functioning tumors were significantly larger in size than the Cushing syndrome-associated tumors (mean 8 cm vs. 4 cm).

WHO classification of RenNETs and its clinical correlation

Three NETs were graded as a G1 (23%), 7 as G2 (54%), and 3 as G3 (23%). The mean Ki67 index of the tumors was 9% (range 2 to 33). The WHO grade was not associated with sex, age, size, hormone-related symptoms, metastases, or patients' outcome (Table 1).

Macroscopic, histological, and immunohistochemical features

Grossly, 54% (7/13) of RenNETs were solid with a red-brown to yellow-brown cut surface (Fig. 1A) and the remaining tumors (46%) were partly cystic (Fig. 1B). Histologically, all non-functioning RenNETs had a distinct reticulated trabecular pattern (Fig. 2A, Table 1) with cubic cells slightly diastase-resistant PAS positive (Fig. 2B), while all the Cushing syndrome-associated RenNETs showed a solid growth pattern with relatively large eosinophilic and granular cells (Fig. 2C). The nuclei of these cells shaped irregular and displayed round macronucleolus and occasionally cytoplasmic eosinophilic inclusion bodies (Fig. 2D).

Immunohistochemically, all tumors were diffusely positive for CK18 and synaptophysin, while chromogranin A was diffusely expressed in both Cushing syndrome-associated RenNETs and in 3/11 non-functioning RenNETs (Fig. 3A, B). INSM1 was diffusely positive in all cases including those with a patchy chromogranin A staining. All non-functioning RenNETs expressed at least one of the pancreatic hormones (6 monohormonal, 5 multihormonal) with somatostatin in 91% (Fig. 3C), followed by PP in 63% and glucagon in 54% of the cases. Insulin and ACTH were negative in all non-functioning tumors. Both Cushing syndrome-associated RenNETs expressed diffusely ACTH (Fig. 3D), while all other hormones were negative except for a patchy somatostatin expression in one case. All non-functioning RenNETs expressed ISL1 (Fig. 3E), while Cushing-associated tumors

were negative (Fig. 3F). SATB2 was diffusely positive in all non-functioning tumors and negative in Cushing syndrome cases. CDX2, TTF1, and PAX8 were consistently negative. Membranous SST2 labeling was found in 49% of non-functioning RenNETs but in none of the Cushing syndrome-associated RenNETs (Table 1).

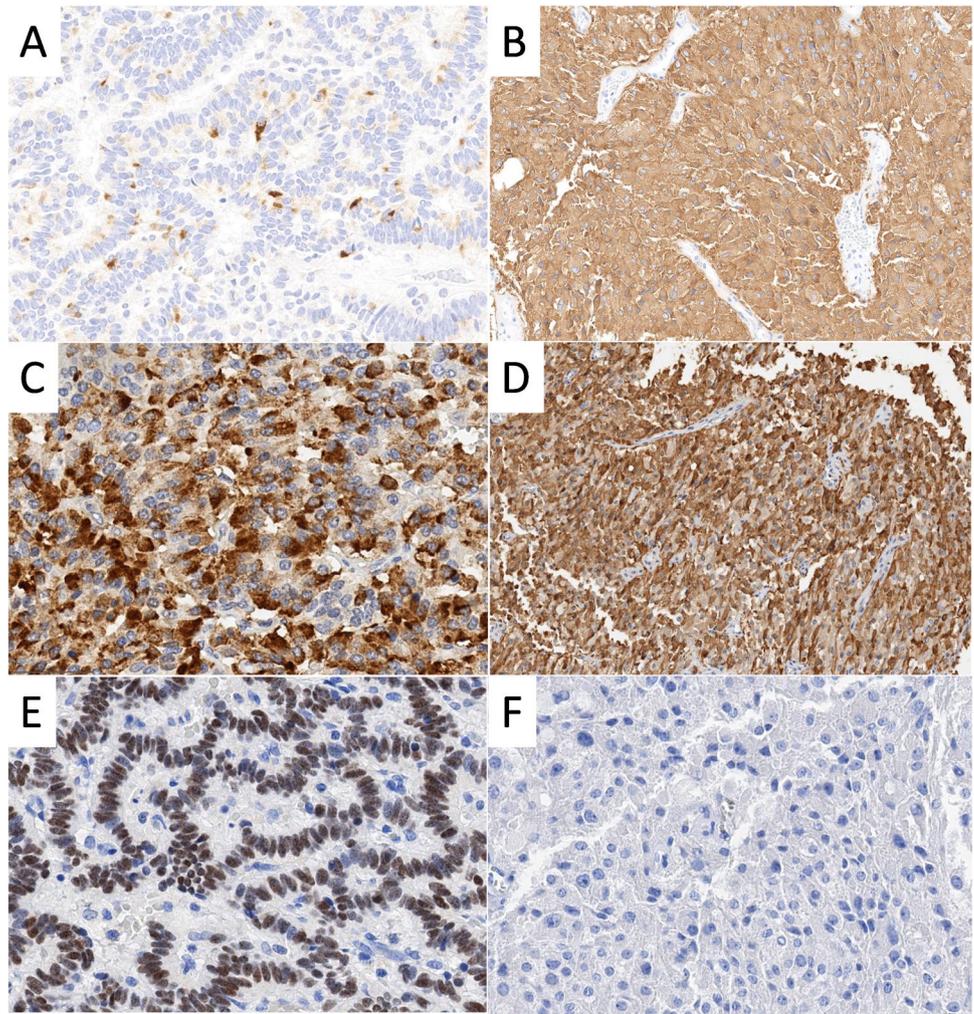

Genetic features

NGS was successfully performed in all tumors. The known NET-related gene alterations such as *ATRX*, *DAXX*, *MEN1*,

or *TSC1/2* or NEC-related genes such as *TP53*, *RB1*, or *PIK3CA*-related genes were not detected in any of the cases. No gene with a pathogenic variant (class 5) was identified. Gene alterations with probably pathogenic variations (class 4) were found in three non-functioning tumors (23%) affecting *SDHA* (case 2), *ARID1B* (case 6), and *ASXL1* (case 9).

Gene alterations of class 3–T4 (variant of unclear significance with probably pathogenic tendency) were found in four non-functioning tumors affecting *PMS2* (case 11), *NUP93* (case 4), *TOP2A* (case 2), and *SNCAIP* (case 3). Other gene changes with unclear pathogenic significance (class 3) are

Fig. 3 Immunohistochemical features of non-functioning (A, C, E) and Cushing syndrome-associated (B, D, F) renal neuroendocrine tumors. **A** Patchy expression of chromogranin A in a non-functioning renal NET and **B** diffuse and strong expression of chromogranin A in a Cushing-associated renal NET. **C** Diffuse somatostatin expression with heterogenous intensity in a non-functioning tumor. **D** Diffuse and strong ACTH expression in a Cushing syndrome-associated tumor. **E** Diffuse and strong nuclear expression of ISL1 in non-functioning tumor and **F** no expression of ISL1 in a Cushing syndrome-associated tumor

listed in Supplementary Table 2. Fusion genes were not detected. The median value of TMB was 0.8 (range 0–5.5). The median MSI quantitative score was 1.72% (range 0–5.88). None of the cases showed a high MSI score (> 10). The tumor with the highest MSI score (5.88 in case 11) showed retained immunohistochemical staining for mismatch repair proteins (MLH1, PMS2, MSH2, MSH6). Loss of SDHB expression was not observed in two cases (case 9 and case 13) with class 2 *SDHD* mutations (Supplementary Table 2).

Literature review

The clinical data of 227 RenNETs extracted from published articles is summarized in Table 2. Of the 194 cases in which hormonal status was documented, 15 (8%) had hormonal symptoms, of which Cushing syndrome was being the most frequent (7/15), followed by carcinoid syndrome (5/15). The remaining three RenNETs with hormonal syndrome included an insulin-secreting tumor with a hypoglycemic syndrome [45], a glucagon-producing tumor with a

glucagonoma-like syndrome [18], and a tumor with a carcinoid-like syndrome [24]. Follow-up data were available in 120 cases (mean 33 months). Large tumor size (6 cm or larger, $p=0.01$) and presence of metastasis at the time of diagnosis ($p<0.001$) were significantly associated with poor patient outcome based on PFS, while age, sex, hormone-related syndrome, and horseshoe kidney were not. Data on WHO grade, available in only 58 cases, and Ki67 index, available in 41 cases, were not associated with outcome. Pancreatic hormone expression was reported to be positive in 60% (6/10) for glucagon, in 50% (7/14) for somatostatin, in 25% (3/12) for PP, and in 59% (7/12) for serotonin. The transcription factor ISL1 was examined in one case and was positive [12], while TTF1 and PAX8 were negative in all examined cases (30 and 27 cases, respectively). Molecular analysis was performed in four studies [15, 34, 44, 53]. Loss of heterozygosity (LOH) on 3p21 was reported in 5 of 11 cases [15, 34, 44]. NGS analysis was performed in 9 RenNETs and revealed variable mutation profiles [44]. The gene abnormalities which were most frequently found included

mutations of *CDH1* and *TET2*, with three mutations in two cases. Next in frequency were LOH 3p and mutations in *AKT3*, *ROS1*, *PIK3P2*, *BCR*, and *MYC* [44].

Discussion

Our study revealed that RenNETs constitute an entity of its own among the various NETs of the body. These usually large tumors have a size-dependent prognosis and a hormonal profile which is pancreas-like, including a high rate of ectopic Cushing syndrome.

All RenNETs in our study, the two Cushing syndrome cases excluded, presented as large tumors with a mean of 8 cm, setting them apart from most of the other NETs of the body such as the digestive (mean 2.6 cm for pancreas) [47] and pulmonary tract (mean 2.4 cm for the lung) [27] and larynx (mean 1.8 cm) [6] and making them comparable to thymus NETs that are usually also large with a similar mean size of 7 cm compared to RenNETs [50]. The reason for the remarkable large size of renal and thymic NETs is probably the location of both organs which allows a silent, symptomless growth for a long time. This unnoticed growth may also explain in RenNET the high rate of metastasis of 73% at diagnosis and in thymic NET the high rate of invasion into adjacent organs or metastasis, which is 60% [50]. Because our RenNET cohort is too small to allow any outcome evaluation, we therefore took the available data from our literature review and found that the 5-year PFS rate of RenNETs is 65% for tumors smaller than 6 cm compared to 31% for tumors 6 cm or larger.

Apart from size, our literature review also revealed that the presence of metastasis at the time of diagnosis has also a prognostic significance with a 5-year PFS rate of 26% vs. 84% in RenNETs without metastases. Surprisingly, we found that the WHO grade, as it is presented in Table 2, was not related to patients' outcome. However, this finding has to be interpreted with caution since the extracted data from literature are limited and probably too small to allow yet any far-reaching conclusions. The reason is that the Ki67-based WHO grading system was only introduced in 2022 to the NETs of the urogenital organ systems [48]. Kim's study from 2019 is the first which applied the Ki67 grading to RenNETs and showed in 6 cases that RenNETs with a Ki67 index above 3% are significantly more often associated with metastasis than those with a Ki67 of less than 3% [29]. Since the Ki67 values of RenNETs of our cohort are generally higher than those in Kim's report, the Ki67 findings in our series of RenNETs, which did not correlate with presence of metastasis, are difficult to compare with those of Kim's study. A study with a higher number of RenNET cases is therefore needed to clarify the prognostic role of the Ki67-based grading in this NET entity.

Two of our RenNETs presented with an ectopic Cushing syndrome. Hormonal syndromes were reported in 14 of 194 cases, of which data on functional activity were available. RenNETs with Cushing syndrome accounted for 50% of all syndromic cases or for 4% of all RenNETs. The second most common syndrome is the carcinoid syndrome, which has been reported in 36% of syndromic cases, but was absent in our cohort. Very rare are insulinoma and glucagonoma with one case each [18, 45]. The high frequency of 15% Cushing syndrome cases among our RenNETs reflects the selection bias that is always associated with a referral case series. However, even if the relative percentage of our Cushing RenNETs is too high, it indicates that an ectopic Cushing syndrome is a feature of this NET entity, which in terms of its frequency has not yet been properly appreciated. The relative frequency of 4% of a Cushing syndrome in RenNETs is comparable with its frequency in pulmonary NETs, in which an ectopic Cushing syndrome is thought to be most frequent in the body, accounting for 4.3% of all pulmonary NETs [36]. It thus seems that RenNETs belong to those NET entities that are most associated with an ectopic Cushing syndrome, which may apart from the pulmonary tumors also include pancreatic and thymic NETs [3, 14].

Regarding the prognosis of RenNETs associated with a Cushing syndrome, our literature search suggests that they share the same prognosis with the non-Cushing syndrome cases, although they present as small tumors with a mean size of 4 cm, probably because of the clinical symptoms that may lead to early detection of the tumors. The two Cushing tumors of our series were classified as G1 and G3, and both patients have no metastasis in the course. In the literature, the Cushing RenNETs had metastasis in half of the cases (3/6). Poorly differentiated NENs of the kidney, usually of the small cell type, have so far not been reported in association with an ectopic Cushing syndrome.

RenNETs with ACTH production and Cushing syndrome are distinct tumors because they not only produce ACTH but also exhibit a special histology. They have a solid histological pattern and an eosinophilic (oncocytic) cytology, which delineate these tumors from the non-functioning RenNETs, that are characterized by cuboidal cells forming a reticulated trabecular pattern. This solid-eosinophilic pattern was also found in the RenNETs with Cushing syndrome reported in the literature, in which exact histological descriptions and/or illustrations were available [10, 19].

ACTH expression in RenNETs was restricted to the patients with Cushing syndrome. ACTH was neither found in any of the trabecular tumors in our series nor in any other non-functioning RenNET reported in the literature. Since the number of our RenNETs which were screened for ACTH is small, it is possible that future studies in larger case series may find ACTH in non-functioning RenNETs, as it has been shown in pulmonary NETs that were systematically screened for ACTH [36].

Another finding that distinguishes the RenNETs with Cushing syndrome from the remaining RenNETs is the differential expression of transcription factors. ISL1 that plays a crucial role in embryogenesis and differentiation of pancreatic beta cells and is frequently expressed in PanNETs [1] but also in duodenal NETs (83%), rectal NETs (75%) [58], and middle ear NETs (100%) [2] was found to be expressed in all non-functioning RenNETs, but not in the Cushing syndrome cases. Similarly, SATB2 that labels the lower gastrointestinal epithelium, and the NETs of the rectum (81%) [58] and middle ear NETs (100%) [5], was only found in non-functioning RenNETs and not in Cushing syndrome-related RenNETs. In contrast, PAX8, TTF1, and CDX2, markers for renal carcinomas, pulmonary and thyroid neoplasms, and small intestine or the appendix, respectively, were constantly negative in all RenNETs of our series and in the cases of the literature [4, 21, 51, 55, 56].

The hormone production in non-functioning RenNETs has so far only been investigated in 14 cases, identifying either PP [23, 46, 53], serotonin [8, 28, 39, 41], or multiple hormones including somatostatin and glucagon [16, 32, 33, 46, 52]. In our series, all the non-functioning tumors expressed at least one of the pancreas hormones (excluding insulin) or serotonin. Although we had two tumors with serotonin expression, none of our RenNETs had a carcinoid syndrome that has been described in 5 of the previously reported cases [40].

Due to the characteristic trabecular morphology, ISL1, and pancreatic hormonal expression, we anticipated a possible genetic similarity between RenNETs and PanNETs. However, none of the investigated tumors showed *MEN1*, *ATRX/DAXX* gene alterations that are detected in approx. 40% of PanNETs [49]. Instead, variable genes were affected in single cases without a definitive pathogenicity. Our results, together with a previous study, indicate that the tumorigenesis of RenNETs is, despite histological and immunohistochemical commonalities with PanNETs, distinct from that of PanNETs. This molecular distinction also argues against an origin of RenNETs from heterotopic pancreatic tissue in the kidney. Moreover, we were unable to find any report on heterotopic pancreatic tissue in the kidney.

In conclusion, RenNETs represent a small but distinct group of NETs. They manifest usually as large tumors with a size above 6 cm, a size that is of prognostic significance. Most RenNETs have a characteristic reticulated trabecular morphology, consistently coexpress ISL1 and SATB2, and are non-functioning, although they express a variety of entero-pancreatic hormones. Biologically and structurally distinct from these RenNETs are the ACTH-positive RenNETs associated with an ectopic Cushing syndrome and displaying a typical solid-eosinophilic morphology in the absence of ISL1 or SATB2 expression. Our literature review reveals that these ACTH-positive tumors belong to

the group of NETs that are most frequently associated with an ectopic Cushing syndrome, such as bronchial, pancreatic, and thymic NETs. The genomic profile completely distinguishes RenNETs from pancreatic NETs including those with a Cushing syndrome.

Supplementary Information The online version contains supplementary material available at <https://doi.org/10.1007/s00428-023-03596-5>.

Acknowledgements The authors would like to thank Dr. Jörg Woźniowski in Pathology Praxis Aurich, PD Dr. Frank Brasch at the Department of Pathology, Klinikum Bielefeld, University Hospital Owl, and Dr. Mathias Sperling at the Department of Pathology, Klinikum Braunschweig, Germany, for submitting cases for consultation and thus made this study possible. We would also like to thank Dr. Andreas Hinkel, Department of Urology, Franziskus Hospital Bielefeld, for providing patients' data.

Author contribution The conception of the study was designed by AK, AA, and GK. Material preparation was performed by AK, NP, KS, IE, WW, AA, and GK. Data collection was performed by AW, JG, NUD, and MP. The data was analyzed by AK, NP, and GK. All authors commented on the manuscript. Manuscript editing was performed by all authors. All authors approved the final version of the manuscript.

Funding Open Access funding enabled and organized by Projekt DEAL. Manfred-Stolte Stiftung and German Research Foundation (DFG), project number 516741100 to AK.

Declarations

Ethical approval This study was approved by the ethic committee of Technical University of Munich (2022–396-DFG-SR).

Conflict of interest The authors declare no competing interests.
