Prediction of Adsorption Equilibria of Gases

Ugur Akgün

Vollständiger Abdruck der von der Fakultät für Maschinenwesen der Technischen Universität München zur Erlangung des akademischen Grades eines Doktor-Ingenieurs
genehmigten Dissertation.

Vorsitzender: Univ.-Prof. Dr.-Ing. Weuster-Botz
Prüfer der Dissertation: 1. Univ.-Prof. Dr.-Ing. A. Mersmann, emeritiert
                         2. Univ.-Prof. (komm. L.) Dr.-Ing. J. Stichlmair, emeritiert

Acknowledgments

I would like to express my deep and sincere gratitude to my supervisor, Professor Dr.-Ing. Alfons Mersmann, em. His wide knowledge and his logical way of thinking were of great value for me. His understanding, encouraging and personal guidance provided an ideal basis for the present thesis.

I am deeply grateful to Professor Stichlmair, who was member of my committee. My sincere thanks are to Professor Weuster-Botz for acting as chairman of my examination. I especially thank Professor Lercher and Dr. Staudt for the help extended to me and the valuable discussion that I had with them during my research.

Special thanks are to Dr.-Ing. PhD Walter Roith for his guidance. Only people like him, who have walked the same rocky way, can understand the efforts we made and the happiness we received.

For giving me the impetus to restart the thesis after a break of several years I would like to thank Dr.-Ing. Axel Eble.

I am grateful to Dr.-Ing. Lutz Vogel for the experiences we shared on the bus route 53 in Munich, Dr.-Ing. Björn Braun for Schafkopfen, Dr.-Ing. Frank Stenger for listening, Dr.-Ing. Lydia Günther for Rock and Roll, Dr.-Ing. Carsten Mehler and Dr.-Ing. Michael Löffelmann for enjoying life in Munich. Especially I would like to thank Carsten Sievers and Manuel Stratmann from the Lehrstuhl für Technische Chemie 2 at the Technische Universität München and Andreas Möller from the Institut für Nichtklassische Chemie e.V. at the Universität Leipzig for investing their limited time in adsorption experiments.

I thank all students and staff at the Lehrstuhl für Feststoff- und Grenzflächenverfahrenstechnik whose presence and spirit made the otherwise gruelling experience tolerable. Especially, I would like to thank Wolfgang Lützenburg and Ralf-Georg Hübner for soccer.

I thank the company Grace Davison for providing zeolite material.

Last but not least I am grateful to my wife Özlem for the inspiration and moral support she provided throughout my research work and for her patience. Without her loving support and understanding I would never have completed my present work.
Apollo and Daphne (1622-1625) from Gian Lorenzo Bernini

Notation and Abbreviations

Latin Symbols

\( A_{i,j} \) - dimensionless interaction parameters

\( \frac{Al}{Si} \) - ratio of aluminium to silicon atoms in the zeolite molecule

\( C \) - parameter in isotherm prediction equation

\( C \) - absorption strength in the IR and UV range

\( C \) J*m\(^6\) interaction constant

\( C \) mol/ m\(^3\) overall concentration of gas

\( D \) m diameter of a particle sphere

\( D_{ax} \) m\(^2\)/s axial dispersion coefficient in a pipe

\( E \) V/m field intensity

\( E \) J potential energy between two molecules or particles

\( F \) N force

\( H_{Ads} \) J/mol specific enthalpy of adsorption

\( H_L \) J/mol specific heat of liquefaction

\( H_e \) mol/(kg*Pa) Henry coefficient

\( H_a \) J Hamaker constant

\( I \) A electrical current

\( I \) J ionisation energy of a molecule

\( IP \) - interaction parameter

\( K \) - effective isotherm slope in concentration pulse method

\( K_L \) 1/Pa Langmuir constant

\( K_T \) \((1/Pa)^m\) Toth constant
L  m  length of a pipe or pore capillary
M  kg/mol  molar mass
N  mol  number of moles
\dot{N}  mol/s  molar flow
N  1/m^3  number density of dipole moments in a volume element
N  -  partial loading in *Langmuir* isotherm
N_A  1/mol  *Avogadro* constant = 6,0225*10^{23} 1/mol
P  C/m^2  electrical polarisation
Q  C*m^2  quadrupole moment
R  -  parameter defined by equation (6.10)
R'  -  parameter defined by equation (8.14)
\Re  J/(K*mol)  universal gas constant = 8,3143 J/(K*mol)
R_m  m^3/mol  molar refraction
R_{m,i}  m^3/mol  molar refraction of the atom or ion
S  m^2  surface
S_{BET}  m^2/kg  specific surface of the adsorbent
T  K  temperature
V  m^3  volume
V  m^3  total volume of gas adsorbed on a solid surface
\dot{V}  m^3/s  volumetric flow rate
W  J  work
a  m/s^2  acceleration
a  -  integration parameter
a_{mol}  m^2/number  average area occupied by a molecule of adsorbate in the
                  *BET* monolayer
\(a_i\) mol/(m\(^2\)s*Pa) BET constant

\(a\) - slope

\(b\) - electronic overlap parameter

\(b\) kg/mol intercept of the linear form of the BET isotherm

\(b_i\) mol/(m\(^2\)s) BET constant

\(b\) - interception value

\(c_0\) m/s speed of light in vacuum= 299792456.2 m/s

\(c\) - BET constant

\(c\) J/(kg*K) heat capacity

\(c\) mol/m\(^3\) gas concentration

\(d\) m tube inner diameter or pore diameter

\(d\) m distance (e.g. between particles)

\(e\) C charge of one electron = 1,60*10\(^{-19}\) C

\(f\) Hz oscillator strength

\(f_{ij}\) - potential factor

\(g\) Pa BET constant

\(h\) J*s Planck's constant = 6,6256*10\(^{-34}\) J*s

\(i\) - complex number \(\sqrt{-1}\)

\(k\) J/K Boltzmann constant = 1,3804*10\(^{-23}\) J/K

\(l\) m distance between positive and negative charges

\(m\) kg mass

\(m\) kg/mol slope of the linear form of the BET isotherm

\(m\) - Toth parameter, \(0 < m < 1\)

\(m_e\) kg mass of one electron = 9,11*10\(^{-31}\) kg

\(n\) - refractive index

\( n^*_x = \frac{n M_j}{v_{micro} \rho_{adsorb}} = \frac{n \beta(T)}{v_{micro}} \) saturation degree or pore filling

\( 1 - n^*_x = 1 - \frac{n M_j}{v_{micro} \rho_{adsorb}} \) residual capacity

\( x = \frac{z}{\sigma_y} \) reduced distance
1. Introduction

The term adsorption denotes the mass transfer of substances from a fluid phase towards a solid surface. Thus, adsorption is a surface effect on solid phases. Accordingly one or more components (adsorptives) of a fluid (liquid or gas) are attached as adsorbate onto solids (adsorbents). The opposite effect is called desorption. Adsorption is a mass transfer mechanism in the two phase system solid/fluid [47]. At a given temperature this mass transfer leads to a thermodynamic equilibrium at which the concentrations of adsorptives and adsorbates remain constant. In the dilute region the solid adsorbate loading is proportional to the partial pressure of the adsorptive. The proportional constant is called Henry coefficient. At higher pressures the loading achieves saturation.

The ability of porous solids to reversibly adsorb large volumes of vapour was detected in the eighteenth century [48]: Lowitz studied in 1785 the effectiveness of charcoal in decolorizing various aqueous solutions and, in particular, its commercial application to the production of tartaric acid. De Sussure reported in 1812 on adsorption experiments of different gases onto porous substances whereas he also described the heat of adsorption. In 1876 Gibbs thermodynamically derived the law of adsorption by describing the relation of surface loading with gas or liquid concentration. Advances towards a quantitative description of the adsorption mechanisms were made in the twentieth century. Besides Freundlich and Toth, Langmuir, in particular, has to be mentioned. In 1916 he derived the theory of monomolecular covering of adsorbed surfaces. This concept was expanded to the theory of multilayer adsorption by Brunauer, Emmet and Teller (BET) in 1938. In 1914 Polanyi introduced the adsorption potential to describe the dependency of the adsorption equilibrium on temperature [24]. Dubinin extended this potential theory in 1959.

The laws of equilibrium thermodynamics, firstly applied to adsorption by Prausnitz in the nineteen sixties, were adopted to gas mixtures by Myers. He developed the theory of ideal adsorbed solutions (IAST) [24]. The developments are still ongoing. A
good example is the multiphase predictive real adsorption theory (MPRAST), by which Markmann described the equilibrium of a non-ideal adsorbate mixture with an energetically non-homogenous solid surface [8].

Some modern concepts have to be mentioned also. With the Hellman-Feynman-Theorem it is possible to specify intermolecular interactions. The basic idea is that the interaction correctly and completely can be described with the help of electrodynamic approaches if the charge distribution of the molecules is known [49]. The charge distribution itself can be calculated by applying the density functional theory as in the COSMO-RS-approach.

Mehler [50] found that it is still not possible to describe real solid surfaces using only theoretical quantum mechanical calculations. Surfaces seem to be too complex and unknown. On the contrary, he used adsorptive molecules with known properties as probes to characterize the solid surface. The interaction of these probes with the adsorbent is the basis in COSMO-RS for calculating the energy distribution of the solids. He quantified the interaction potentials of the solids via the Henry-coefficients determined by adsorption experiments.

It seems that Henry-coefficients are very important not only for describing the adsorption itself but also for characterizing the solid surfaces. The basis of all adsorption processes and theories is the single-component adsorption equilibrium and especially the Henry-coefficient. Maurer established an innovative way for a priori calculating Henry-coefficients, based only on gas and solid properties. He analysed very successfully the interaction of gases with energetically homogenous microporous adsorbents like activated carbon.

Nevertheless, there is no general model for the description of adsorption of any polar or nonpolar gases on any polar or nonpolar microporous adsorbent. After removing this deficiency it would be possible to improve the prediction not only of multicomponent adsorption problems which are real engineering tasks. Also the characterisation of solid surfaces with density functional theories would be one important step closer.
2. Objective

Hydrogen plays an eminent role in the processing of fuels and can become important for engines in motorcars with respect to CO$_2$-emissions. An important task is the design of a new unit for the purification of a contaminated hydrogen gas in a petrochemical plant. This gas is used in heterogeneous hydrogenation reactors with fixed bed catalysts. The separation of the contaminants from hydrogen leads to a very pure hydrogen feed to the reactors resulting in an improved selectivity. The tail gas of the separation no longer burdens the capacity of the whole petrochemical plant and can be burned as recycled fuel gas in the cracking furnaces. A feasible process is a pressure swing adsorption unit to purify the hydrogen stream. When planning this new separation process an engineer has to consider the two main general aspects

- phase equilibrium and
- mass transfer dynamics.

Understanding the mass transfer dynamics aids the calculation of the time required for the process. In the above example it is the time until the adsorption beds are on the verge of a breakthrough of contaminated hydrogen feed. For continuous operation it is necessary to switch the feed from this loaded adsorber to a second one which is fresh regenerated. In modern concepts automated programs control the switching matrix of the adsorber valves. The dynamics of the process yields the information when to switch the valves so that the whole capacity of the adsorbers can be used without letting contaminated gas through.

The first aspect is the equilibrium of the materials in the separation process itself. It gives the engineer information about the amount of adsorbent required to remove the impurities in hydrogen stream and to calculate the size of the apparatus. In combination with the dynamics of the process two general engineering challenges can be optimised: Maintaining a constant high quality of the product and reducing expenses.
In adsorption processes or adsorption steps of physical, chemical or biological reactions the adsorption isotherm is the most used description method of the phase equilibrium. Knowledge of phase equilibria is the key for understanding complicated processes. Engineers need these isotherms in the planning of production processes. On the other hand it consumes both time and manpower to determine the isotherms by costly experiments.

Besides engineering aspects the scientific viewpoints of adsorption are of great interest when developing new materials and processes. The physical behaviour of complex systems of gases and solids often depends on the adsorption of the educts. For instance, in heterogeneous catalysis gas molecules adsorb on the catalyst surface, and reactions in the adsorbed monolayer lead to products which are desorbed from the surface.

Many processes and reactions in the chemical industry and in chemical science are based upon heterogeneous catalysis. Three important questions of these processes are the understanding of the reaction, the development of the catalyst and the design and optimisation of the reactor. All aspects can benefit from a rigorous and accurate kinetic modell. Especially the competition for adsorption sites is very important for the kinetics of a heterogeneous catalytic reaction if it is the rate determining step. It refers then to the slowest step of the reaction process and controls the activity [123]. A prerequisite for kinetic modelling is the knowledge of adsorption equilibria.

Therefore, the adsorption equilibrium of the gaseous educts with the catalyst surface is related to the reaction rate and also the amount of molecules occupying the free adsorption sites. In both main model mechanisms of heterogeneous catalysis (Langmuir-Hinshelwood and Elay-Rideal) the adsorption isotherm is needed to calculate the effective reaction rate in dependence of the partial pressures of the reactants. Therefore adsorption equilibria are not only eminent for the understanding of the process of heterogeneous catalysis but also for the development of novel catalysts and adsorbents.
In the literature the isotherm of interest is not always available. Concepts like COSMO-RS are very promising but too complex for daily engineering work. Also adaptations on the isotherm data like Langmuir and Toth can not always be extrapolated to other gas-solid systems. There is no general model to describe the adsorption of any polar or nonpolar gas by any polar or nonpolar microporous adsorbent.

The objective of this study is driven by this demand. First, the fundamentals of adsorption will be examined in this work. The engineer and scientist will get an overview over microporous adsorbents, methods of measurement and the different isotherm descriptions. There will be a Section about characterisation of solid surfaces. Because there is a lack of data regarding Hamaker constants of microporous solids an advanced Hamaker-de Boer model will be introduced to calculate this dispersion coefficient.

Henry coefficients of adsorption will a priori be calculated based on gas and solid properties of the molecules. In the case of nonpolar gas – nonpolar solid, polar gas – nonpolar solid and nonpolar gas – polar solid an analytical equation will be introduced to directly calculate the Henry coefficients. This approach will be expanded to the fourth case of polar gas – polar solid so that the whole spectrum of possibilities is covered. A novel model for predicting the complete adsorption isotherm based only on the molecular properties will be introduced. The model will be verified with own experimental and literature data.

After a discussion of the experimental and theoretical results there will be a conclusion and an outlook to future demands. The experimental methods and materials of the work will be explained in the appendix together with lists of the properties of the examined adsorptives and adsorbents.
3. Fundamentals of Adsorption

3.1. Introduction

Although adsorption has been known as a physical process since the 18th century new aspects are generated through the demands of modern engineering and science in the 21st century.

On the one hand the industry, especially the chemical one, has to improve itself permanently. The understanding of adsorption is a key for future improvements. To withstand the global competition the industry has to enhance its effectiveness continuously. Manpower and invests need to be adopted very carefully at the right time. So modern engineers need powerful instruments to base their decisions on solid technical fundamentals. These instruments need to be economic, usable in a wide range of applications and easy to learn. This study provides such an instrument for the field of adsorption.

On the other hand science also has made great advances and still continues to. Adsorption seems to be a fundamental physical step in a wide range of research fields. For example in medical biochemistry the interaction of cells with biomaterials is dependent on the adsorption layer of proteins [51]. Another example is the storage of hydrogen through reversible adsorption in metallic hydrides. Also the adsorption step of reactants on solid surfaces is eminent for the field of heterogeneous catalysis.

The aim of Chapter 3 is to give a brief overview on the state of research and the literature regarding adsorption science and processes.

3.2. Adsorbents

Development and application of adsorption cannot be considered separately from development of the technology of manufacture of adsorbents applied both on the laboratory and industrial scales. These sorbents can take a broad range of chemical
forms and different geometrical surface structures. This is reflected in the range of their applications in industry, or helpfulness in the laboratory practice [52]. Table 3.1 shows the basic types of industrial adsorbents.

**Table 3.1**: Basic types of industrial adsorbents.

In this work emphasis is laid on microporous adsorbents like activated carbon and zeolites, especially aluminosilicates. These sorbents play an important role in industry.

**3.2.1. Activated carbon**

Since our early history active carbon has been the first widely used adsorbent. Its application in the form of carbonised wood (charcoal) was described as early as 3750 BC in an ancient Egyptian papyrus [52].

Nowadays commercial sources for activated carbons include biomass materials (wood, coconut shell and fruit pits) and fossilized plant matter (peats, lignites and all ranks of coal) or synthetic polymers [53]. Activated carbon is normally made by thermal
decomposition of carbonaceous material followed by activation with steam or carbon
dioxide at elevated temperature (700 – 1100°C). The activation process essentially
involves the removal of tarry carbonisation products formed during the pyrolysis,
thereby opening the pores [48]. It is generally believed that carbon dioxide activation
mainly causes the creation of microporosity while steam activation results in the
development of mesoporosity to a higher extent. These types of activation are known
as the physical methods and are widely used in industries.

Important parameters that determine the quality and yield of activated carbons are the
final temperature of activation and dwell time at this temperature [54]. Effects of dwell
time and activation temperature on the BET surface area and micropore volume of
activated carbons made from pistachio-nut shells are shown in figure 3.1 and in figure
3.2 respectively. Also the CO₂ flow rate and the heat rate have an impact.

The structure of activated carbon consists of elementary micro crystallites of graphite,
but these micro crystallites are stacked together in random orientation. The spaces
between the crystals which form the micropores. The pore size distribution is typically
trimodal [48]. Characteristic properties of activated carbons used for gas purification
are listed in table 3.2 [24].

3.2.2. Zeolites

The main class of microporous adsorbents are zeolites which comprise, according to a recommendation of Structure Commission of the International Zeolite Association, not only aluminosilicates but also all other interrupted frameworks of zeolite-like materials, e.g. aluminophosphates [52]. In this study emphasis is laid on aluminosilicates like MS4A, MS5A, NaX and NaY which are widely used in industry.

The term zeolite was originally coined in the 18\textsuperscript{th} century by a Swedish mineralogist named Axel Fredrik Cronstedt who observed, upon rapidly heating a natural mineral, that the stones began to dance about as the water evaporated. Using the Greek words which mean "stone that boils" he called this material zeolite.

The elementary building units of zeolites are SiO\textsubscript{4} and AlO\textsubscript{4} tetrahedrons. Adjacent tetrahedrons are linked at their corners via a common oxygen atom, and this results in an inorganic macromolecule with a structurally distinct three-dimensional framework. It is evident from this building principle that the net formulae of the tetrahedrons are SiO\textsubscript{2} and AlO\textsubscript{2}, i.e. one negative charge resides at each tetrahedron in the framework which has aluminium in its centre. The framework of a zeolite contains channels, channel intersections and/or cages with dimensions from ca. 0.2 to 1 nm. Inside these voids are water molecules and small cations which compensate the negative framework charge [55].

Figure 3.3 shows the principle construction of a zeolite. The smallest unit is the primary building unit (PBU) which consists of SiO\textsubscript{4} or AlO\textsubscript{4} tetrahedrons. These tetrahedrons are linked together via oxygen ions to secondary building units (SBU). The SBUs can be of cubic form or a hexagonal prism or an octahedron. They are knotted to \(\beta\)-cages which are linked again via the oxygen ions [56].

The chemical composition of a zeolite can, hence, be represented by a formula of the type \(M_{\nu\nu}\nu((AlO_2)\nu(SiO_2)\nu)\nu^*H_2O\) [57] with \(\nu\) the number of valence electrons of the cation \(M\) (Na\textsuperscript{+}, K\textsuperscript{+}, Ca\textsuperscript{++}, Mg\textsuperscript{++}). The numbers \(x\) and \(y\) are integers and the ratio \(y/x\) is equal or bigger one, \(z\) is the number of water molecules in the zeolite unit cell [57].
Figure 3.3: Principle construction of a zeolite of LTA type [56].
Until today approximately 40 natural zeolites have been found. As the consequence of successful synthesis work more than 100 new zeolites were produced. Most of the zeolites are manufactured via so-called hydrothermal synthesis. These are reactions in aqueous solution with temperatures above 100°C, similar to the natural conditions. In the laboratory the sources for the reactions are sodium silicate or silica sol as the SiO₂-origin and hydrated aluminium hydroxide or aluminates as the Al₂O₃-origin. The two sources react with strong bases like NaOH or KOH under hydrothermal conditions and pressure in autoclaves. The reaction time can be between several minutes and months [58].

Zeolites are applied in many fields.

- One characteristic property is the ability of ion exchange. Zeolite A can exchange its sodium ions with the calcium ions in water which becomes then “softer”. The calcium enriched zeolites are discharged with the waste water.

- Zeolites can act as acid catalysts in chemical reactions because the alkali metal ions can be exchanged with protons. This happens in the inner cavities, so zeolites can be handled without danger.

- Another application is the use of zeolites as chemical sensors for detecting gases like NH₃ in exhausts of automobiles or power plants. It seems that protons can migrate through the zeolite cavities. This causes a change in the ionic conductivity which is measurable.

- For this work the adsorption of gases or vapours is eminent. As adsorbents they can capture air moisture or solvent vapour. They are used in the clearance of multiple composite glasses or for drying of refrigerants in cooling circuits or brake systems.

- Sterical effects of zeolites are neglected in this study. However they can be very important in many chemical processes like filtering linear hydrocarbons out of petrol to get it knockproof and, in general, separation of mixtures.
3.2.3. Silicalite-1

Silicalite-1 was firstly introduced by Flanigen as a new hydrophobic but organophilic polymorph of silica. This new polymorph was topologically very similar to ZSM-5 so it was considered as the aluminium free end member of MFI type zeolites. It contains two types of channel systems with similar size: straight channels and sinuous channels. The diameters of these channels are about 0.54 nm. These two different channels are perpendicular to each other and generate intersection areas which have 0.89 nm of diameter. Silicalite-1 has ten membered oxygen pore openings, and has high thermal and acidic stability. The comparable pore size of silicalite-1 channels with industrially important small organic molecules like methane, n-butane, n-octane and ethanol makes it important for many applications [59]. Silicalite-1 provides a non-polar structure [133]. It is, therefore, considered as a model adsorbent for testing adsorption isotherm models, based on gas-solid molecular interactions [60].

3.3. Characterising microporous solids

Most analysis techniques typically probe a particular aspect of the material and, consequently, a combination of methods is necessary to give a balanced description of complex solids [61]. Microporous adsorbents have very different properties which are fundamental for the process of adsorption. Their properties can influence the equilibrium and/or the dynamics of adsorption. Although this study is mainly about gas adsorption equilibria also dynamical aspects should be mentioned because engineers need both information for planning industrial or laboratory processes. The dynamic and steady state properties of the solids can be found by characterising them through following factors:

- Specific surface
- Porosity
- Density
- Chemical composition
- Refractive index
- Hamaker constant
3.3.1. Specific surface

There are interactions of molecules on every interface between a solid and a fluid – gas or liquid- phase which can lead to attraction or repulsion forces. In the case of attraction a two dimensional interaction phase is composed with the thickness of molecule dimensions. This phenomenon is usable for technical purposes if this interface has sufficient dimensions and if it is accessible for the molecules. The surfaces of microporous adsorbent have magnitudes of several hundred square meter per gram solid [24].

From type II and type IV isotherms, the specific surface area of the adsorbents can be determined by applying the BET method [61]. Brunauer, Emmett and Teller have derived an equation for the adsorption of gases on solids with n layers [62]:

\[
\frac{V_G}{V_{G,\text{mon}}} = \frac{c \varphi}{(1 - \varphi)} \cdot \frac{1 - (n + 1)\varphi^n + n\varphi^{n+1}}{1 + (c - 1)\varphi - c\varphi^{n+1}}
\]

(3.1)

where \( V_G \) is the total volume of gas adsorbed on the solid surface, \( V_{G,\text{mon}} \) the volume of gas adsorbed in a monolayer, \( \varphi \) the ratio of pressure to saturation pressure of the gas. The parameter \( c \) is a dimensionless constant and dependent from the enthalpy of adsorption in the first layer and the heat of evaporation. The assumption made by Brunauer, Emmett and Teller is that the evaporation-condensation properties of molecules in the second and higher adsorbed layers are the same as those of the liquid state.

If we deal with adsorption on a free surface, then at the saturation pressure of the gas an infinite number of layers can build up on the adsorbent. \( n \to \infty \) one leads to

\[
\frac{V_G}{V_{G,\text{mon}}} = \frac{c \varphi}{(1 - \varphi)} \cdot \frac{1}{1 + (c - 1)\varphi}
\]

(3.2)
With the law of ideal gases and the balance of the mass of the adsorbent equation (3.2) becomes

\[
\frac{n}{n_{\text{mon}}} = \frac{c\varphi}{(1 - \varphi)} \cdot \frac{1}{1 + (c - 1)\varphi}
\]  

(3.3)

where \( n \) is the overall loading of the adsorbent and \( n_{\text{mon}} \) the monolayer loading. From this the linear form \( y = b + m\varphi \) can be derived to obtain the specific surface of the adsorbent due to the BET adsorption isotherm:

\[
\frac{\varphi}{n(1 - \varphi)} = \frac{1}{n_{\text{mon}}c} + \frac{(c - 1)}{n_{\text{mon}}c}\varphi
\]  

(3.4)

The intercept, \( b = \frac{1}{n_{\text{mon}}c} \), and the tangent of the gradient angle, \( m = \frac{(c - 1)}{n_{\text{mon}}c} \), permit the calculation of the monolayer loading \( n_{\text{mon}} \) and the BET constant \( c \):

\[
n_{\text{mon}} = \frac{1}{b + m}
\]  

(3.5)

\[
c = \frac{m}{b} + 1
\]  

(3.6)

Finally the BET surface area is calculated from

\[
S_{\text{BET}} = n_{\text{mon}} a_{\text{mol}} N_A
\]  

(3.7)

Here \( a_{\text{mol}} \) denotes the average area occupied by a molecule of adsorbate in the completed monolayer and \( N_A \) the Avogadro constant [63].

By convention, most surface area determinations are based on the area occupied by a nitrogen molecule. The nitrogen adsorption is measured at the boiling point of nitrogen, 77.4 K. The value of \( a_{\text{mol}} \) may be estimated following an early suggestion of Emmett and Brunauer from the density of liquid nitrogen at 77.4 K. The estimate uses
the assumption that the packing density of adsorbed nitrogen on a surface is the same as in the liquid. This leads to the equation

$$a_{mol} = 1.091 \left( \frac{M}{\rho L N_A} \right)^{\frac{7}{2}}$$  \hspace{1cm} (3.8)

where $M$ is the molar mass of nitrogen (0.028 kg/mol), $\rho_L$ the density of liquid nitrogen (810 kg/m$^3$) and 1.091 is a packing factor for 12 nearest neighbours in the bulk liquid and six on the plane surface. Insertion of these quantities and of the Avogadro constant into equation (3.8) gives $a_{mol}(N_2) = 0.162$ nm$^2$ for nitrogen at 77.4 K.

For practical purposes, the average area occupied by other molecules can be determined by comparison of their monolayer capacity with that of nitrogen. Using this method, the areas occupied by argon $a_{mol}(Ar)$ and krypton $a_{mol}(Kr)$ at 77.4 K were then determined to be 0.138 nm$^2$ and 0.2 nm$^2$, respectively.

### 3.3.2. Pore volume distribution

The word pore comes from the Greek word ‘πορος’ which means passage. This indicates the role of a pore acting as a passage between the external and the internal surfaces of a solid, allowing material, such as gases and vapours, to pass into, through or out of the solid. Almost all adsorbents used in catalysis or for purification/separation purposes have a high porosity, and this porosity is the only practical method of introducing greatly enhanced surface areas into a solid [64]. Porosity has a classification system as defined by IUPAC which gives a guideline of pore widths applicable to all forms of porosity. Distinctions in porosity classes are not rigorous and they may often overlap in size and definition. The widely accepted IUPAC classification is as follows:

$$d_{\text{Micropores}} < 2 \text{ nm}$$

$$2 \text{ nm} < d_{\text{Mesopores}} < 50 \text{ nm}$$

$$d_{\text{Macropores}} > 50 \text{ nm}$$
There are several methods to measure pore related parameters of a solid. Here exemplarily the mercury porosimetry and the t-plot method of de Boer shall be discussed in detail. The other common methods are listed in Table 3.3 [67]:

**Table 3.3: Methods to measure pore related parameters of a solid.**

</tbody>
</table>
In mercury porosimetry mercury is injected into the pores of the solid to measure the pore size and the pore volume distribution. The gas is evacuated from the sample cell and mercury is then transferred into the sample under vacuum and pressure is applied to force mercury into the sample. In the theoretical model of Washburn [66] all pores are treated as cylindrical pores with an inner radius \( r \). The mercury with the pressure \( p \) is balanced with the surface tension \( \gamma \) of mercury. This leads to

\[
p r = -2 \gamma \cos \beta
\]

(3.9)

with \( \beta \) the contact angle of the mercury with the pore surface. A typical value for \( \beta \) is 140 degrees and for the surface tension 484 mN/m or 0.484 J/m\(^2\).

The Washburn equation (3.9) can be derived from the equation of Yang and Dupré [65]:

\[
\gamma_{SG} = \gamma_{SL} + \gamma_{LG} \cos \beta
\]

(3.10)

where \( \gamma_{SG} \) is the interfacial tension between solid and gas, \( \gamma_{SL} \) the interfacial tension between solid and liquid, \( \gamma_{LG} \) the interfacial tension between liquid and gas and \( \beta \) the contact angle of the liquid on the pore wall. It is derived from a force balance as seen in figure 3.4 [49].

![Figure 3.4: Force balance of a mercury drop on a solid surface.](image)

The work, \( W \), required for moving the liquid up the capillary when the solid-gas interface disappears and solid-liquid interface appears is
\[ \Delta S = \gamma_s l - \gamma_s g \Delta S \]  
\[ (3.11) \]

where \( \Delta S \) is the surface of the capillary wall covered by liquid when its level rises. With equation (3.10) it is

\[ W = -\gamma_L g \cos \beta \Delta S \]  
\[ (3.12) \]

The work required to raise a column of liquid in a capillary with the radius \( r \) is identical to the work necessary to force liquid out of the capillary. If a volume \( V \) of liquid is forced out of the capillary with a gas at a constant pressure \( p \), the work \( W \) is

\[ W = V \ p \]  
\[ (3.13) \]

A combination of equations (3.12) and (3.13) gives

\[ V \ p = -\gamma_L g \cos \beta \Delta S \]  
\[ (3.14) \]

When the capillary is circular in cross-section, parameters \( V \) and \( \Delta S \) are given by \( \pi r^2 L \) and \( 2 \pi r L \), if \( L \) is the length of the capillary. Substituting these terms into equation (3.14) yields the Washburn equation (3.9), which relates the pressure of the mercury to the radius of the pores via an indirect proportionality.

The interrelationship of the differential volume \( dV \) with the differential radius \( dr \) is given with a pore volume distribution function \( f(r) \)

\[ dV = f(r) \ dr \]  
\[ (3.15) \]

The Washburn equation (3.9) can be rewritten in

\[ dr = -\frac{r}{p} dp \]  
\[ (3.16) \]

The combination of the equation (3.15) with (3.16) yields
\[ f(r) = -\frac{p}{r} \left( \frac{dV}{dp} \right) \]  

(3.17)

With equation (3.17) the pore radius \( r \) is related to the pore volume distribution \( f(r) \). Another illustration can be found with the relationship

\[ \frac{p}{dp} = -\frac{r}{dr} \]  

(3.18)

combined with

\[ r \cdot f(r) = -\frac{p}{dp} dV = \frac{d}{dr} dV = \frac{dV}{d\ln r} \]  

(3.19)

Therefore, the distribution function \( f(r) \) and the related volume distribution \( dV/d\ln r \) can be calculated.

Another method for measuring pore volumes is the t-plot method [63]. The t-plot method is most commonly used to determine the external surface area and micropore volume of microporous materials. It is based on standard isotherms and thickness curves which describe the statistical thickness of the film of adsorptive on a non-porous reference surface.

For a large number of non-porous solids the shape of the nitrogen isotherm can be represented with a single curve, by plotting the ratio \( \frac{V_{N_2}}{S} \) as a function of the relative pressure \( \frac{p}{p^0} \). \( V_{N_2} \) denotes the volume of \( N_2 \) adsorbed, \( S \) the surface area of the sample, \( p \) and \( p^0 \) the partial and saturation pressure of nitrogen, respectively. The resulting t-curve reflects the statistical thickness \( t \) of the adsorbed nitrogen multilayer and can be calculated according to:
\[ t(nm) = 0.1 \sqrt{\frac{13.99}{0.034 + \log\left(\frac{p^0}{p}\right)}} \]  \hspace{1cm} (3.20)

Deviations of the t-plot from the ideal behaviour allow the deduction of the nature of pores and the determination of the micropore volume (figure 3.5). Curve a in figure 3.5 is linear and starts at the origin, which indicates an ideal t-material. Therefore, \( S \) can be calculated from the tangent. Curve b shows a strong upward deviation from linearity at a certain pressure \( \frac{P}{P^0} \), which indicates that starting from \( t_1 \) capillary condensation takes places in addition to adsorption. In contrast, if some narrow pores are filled by multilayer adsorption according to curve c further adsorption does not occur in this part, as that surface has become unavailable. At this point the t-plot begins to deviate downwards from the straight line at \( t_2 \). This situation is, for instance, encountered in the presence of slit-shaped pores. The presence of micropores is indicated by a positive intercept at the y-axis as shown in line d. A straight line is found and the surface \( S \) can be calculated from this tangent. The positive intercept point is caused by a relatively large nitrogen uptake at very low t-values. Such a high nitrogen uptake at very low pressures is due to the strong adsorption in micropores and, hence, allows to calculate the micropore volume \( v_{micro} \) from the intercept.

**Figure 3.5**: Different courses of the t-plot.
For more detailed descriptions and theories to porosity and measurement methods reference should be made to the literature [68].

3.3.3. Density and porosity

The density of a porous solid is the relation of its mass \( m_S \) to its volume \( V_S \) without the pore volume:

\[
\rho_S = \frac{m_S}{V_S}
\]  

(3.21)

Pycnometric density is at the moment the closest approximation of true density [70]. The term pycnometer is derived from the Greek word “πυκνοσ”, meaning dense, and meter. With this method the pores are filled with gas molecules [69]. Helium is recommended as probe gas [69] because:

- it is atomic and very close to ideal gas behaviour,
- it is not adsorbed at room temperature,
- its atoms are very small to diffuse also into smallest pores and
- it has a high heat transfer coefficient to adapt the chamber temperature very quickly.

Figure 3.6: Draft of a gas pycnometer.
V₁, V₂ and V₃ are the calibrated volumes of the measurement chamber and the extra volumes for expansion of the measurement gas. V₉ is the volume of the gas in the measurement chamber with the sample in it. After weighting the chamber without \((m_{\text{chamber}})\) and with the sample \((m_{\text{chamber+sample}})\) the mass of the sample can be calculated.

\[
m_{\text{sample}} = m_{\text{chamber+sample}} - m_{\text{chamber}} \tag{3.22}
\]

In the first step the sampled chamber is filled with a well chosen gas and the pressure \(p₁\) after equilibrium is measured. In the second step the valve \(v₂\) between the measurement chamber and the small expansion chamber is opened followed by a second pressure measurement \(p₂\). With the law of ideal gases it follows

\[
p₁ V₉ = p₂ (V₉ + V₂) \tag{3.23}
\]

or

\[
V₉ = \frac{V₂}{p₁ - 1} \tag{3.24}
\]

For the true density it follows:

\[
ρₜ = \frac{m_{\text{chamber+sample}} - m_{\text{chamber}}}{V₁ - \frac{V₂}{p₁ - 1}} \tag{3.25}
\]

In order to calculate the volume of the pores the helium in the measurement chamber is moved by a pump. The chamber (with the solid in it) is filled again with mercury under atmospheric conditions. The mercury encapsulates the solid without penetrating into the pores. So it is possible to calculate the pore volume of the sample:
Finally the porosity of the microporous adsorbent is

\[
\varphi = \frac{V_{\text{pores}}}{V_{\text{pores}} + V_s} = \frac{V_2}{p_1 / p_2 - 1} - V_{\text{mercury}} = \frac{V_2}{p_1 / p_2 - 1} - V_{\text{mercury}} = \frac{V_2 / V_{\text{mercury}} (1 / p_1 / p_2 - 1) - 1}{V_{\text{mercury}} - 1} \tag{3.27}
\]

The apparent density of the microporous solid is

\[
\rho_{\text{app}} = \frac{m_{\text{chamber+sample}} - m_{\text{chamber}}}{V_{\text{pores}} + V_s} = \frac{m_{\text{chamber+sample}} - m_{\text{chamber}}}{V_1 - V_{\text{mercury}}} \tag{3.28}
\]

and defined as the ratio of mass of the solid adsorbent to the volume of the solid inclusive the pore volume.

### 3.3.4. Chemical composition and structure

The chemical composition and the structure of a solid play an important role for polarity and adsorption behaviour similar to the density and the porosity. Zeolites are the main interest of this study so emphasis is laid on composition of aluminosilicates.

The structures of zeolites consist of three-dimensional frameworks of SiO\textsubscript{4} and AlO\textsubscript{4}\textsuperscript{-} tetrahedron. The aluminium ion is small enough to occupy the position in the centre of the tetrahedron of four oxygen atoms, and the isomorphous replacement of Si\textsuperscript{4+} by Al\textsuperscript{3+} produces a negative charge in the lattice. The net negative charge is balanced by exchangeable cations (sodium, potassium, or calcium). The ratio of silicon to aluminium ions cannot be less than one and is infinite in silicalite-1. Zeolite synthesis is already explained in Section 3.2.2. The size of the cage window is determined by the number of oxygen atoms in the ring. A consequence is the physical effect of sieving molecules out of a gas mixture. In table 3.4 important zeolites are listed [24].

The molecule diameter can be calculated with the \textit{van-der-Waals} volume $v_{vdW}$ (in m$^3$/mol) which is defined as [26]

$$v_{vdW} = \frac{\mathcal{R} T_c}{8 p_c}$$  \hspace{1cm} (3.29)

where $c$ relates to critical properties of temperature and pressure and $\mathcal{R}$ is the universal gas constant. With the assumption that the gas molecule is a sphere the molecule diameter can be calculated. With

$$\frac{v_{vdW}}{N_A} = V_{sphere} = \frac{4}{3} \pi \left( \frac{d}{2} \right)^3$$ \hspace{1cm} (3.30)

it follows for the molecule diameter in m that

$$\sigma_i = \sqrt[3]{\frac{3 \mathcal{R} T_c}{16 p_c N_A \pi}}$$ \hspace{1cm} (3.31)

With equation (3.29) and table 3.5 it can be decided whether or not a zeolite is suited for a technical sieving process.

\textbf{3.3.5. Refractive index}

It will be shown later that the refractive index $n$ and the interacting energies $\Phi_{ij}$ between adsorptive and adsorbent molecules are key parameters in order to calculate adsorption equilibria. Adsorptive molecules can be nonpolar or polar with a dipole moment $\mu_i$ and/or a quadrupole moment $Q_i$. In polar molecules the centres of the positive and negative charge $q$ have the distance $l$:

$$\mu_i = q_i \cdot l$$ \hspace{1cm} (3.32a)

If two dipoles with counterdirection are effective in an adsorptive molecule a quadrupole $Q_i$ can be effective.
With respect to zeolite molecules the anions and cations lead to an electrical field with the strength \( E \) according to

\[
E = \frac{q}{4\pi\varepsilon_0 r^2}
\]

(3.32b)

with \( \varepsilon_0 \) as the electrical permittivity in vacuum and \( r \) is the distance between the charges. In electrical fields a dipole moment \( \mu_{i,\text{ind}} \) can be induced in an adsorptive molecule according to

\[
\mu_{i,\text{ind}} = \alpha_i E = \left[ (\alpha_i)_\text{unpolar} + \frac{\mu_i^2}{3kT} \right] E
\]

(3.32c)

The polarisability \((\alpha_0)_i\) of nonpolar or \(\alpha_i\) of polar molecules are defined by this equation. The interaction energies \(\Phi_{i,\text{ind}}\) according to induced dipoles, \(\Phi(\mu_i)\) according to permanent dipoles \(\mu_{i,\text{ind}}\) and \(\Phi(Q_i)\) due to a quadrupole moment \(Q_i\) are

\[
\Phi_{i,\text{ind}} = -\frac{\alpha_i}{2} E^2
\]

\[
\Phi(\mu_i) = -\mu_i E \quad \text{and} \quad \Phi(Q_i) = -\frac{Q_i}{2} \frac{\partial E}{\partial r}
\]

(3.32d)

As mentioned above the refractive index is one of the important parameters describing the optical properties of solid materials. In general it is difficult to obtain a quantitative relation between the refractive index and the structure as well as composition of materials. It seems that the refractive index is dependent on atomic parameters like mass, radius and electric charge of the ions constituting the material [71]. According to classical dielectric theory, the refractive index depends on the density and on the polarisability of the atoms in a given material [72]. The polarisability of a microporous adsorbent determines its disperse properties and,
thus, it is possible to calculate the Hamaker constant from knowledge of the refractive index [41]. In [73] refractive indices of multicomponent silicate melts containing alumina have been determined employing a high temperature ellipsometer. The data were used to propose a predictive equation for the refractive indices of silicate melts. In [72] 13 SiO₂ polymorphs with topologically different tetrahedral frameworks have been investigated in order to find a relationship between refractive index and density. The mean refractive indices of the guest free porosils were determined by the immersion method using the NaD line. One example is the ZSM-5 type zeolite silicalite-1 examined by Marler [72]. Another possibility is the method of Becke lines. A Becke line is a bright halo near the boundary of a transparent particle, which moves with respect to that boundary when the microscope is moved up and down. The halo will always move up the higher refractive index medium as the position of the focus is raised. The halo crosses the boundary to the lower refractive index medium when the microscope is focused in downward direc. The results are compared with pure, isotropic crystalline solids with known refractive indices (e.g. NaCl, CaCO₃). Van der Hoeven measured with this method the refractive index of zeolite MS4A [41].

There are several approaches for quantitatively describing the refractive index. Three of them will be explained in this study. Neglecting interactions between the atoms the classical dielectric theory leads to the Newton-Drude relation

\[
\frac{n_{\text{solid}}^2 - 1}{\rho_{\text{app}}} = \frac{\bar{\alpha}_{\text{solid}} N_A}{\varepsilon_0 M_{\text{solid}}} = \text{const.}
\]

(3.32e)

where \( M_{\text{solid}} \) is the molar mass of the solid in kg/mol, \( \bar{\alpha}_{\text{solid}} \) the mean average polarisability in \((C^2*m^2)/J\), \( \pi_{\text{solid}} \) the mean refractive index, \( \varepsilon_0 \) the permittivity of free space in \( C/(V*m) \) and \( \rho_{\text{app}} \) the apparent density of the solid in kg/m³.

The second approach takes into account interactions between the atoms and the fact that the dielectricum is not continuous. This is known as the Lorentz-Lorenz assumption. It leads to the Clausius-Mosotti equation of nonpolar but polarisable molecules (for a detailed derivation of this theory see Arndt and Hummel):
\[
\frac{n^2 - 1}{(n^2 + 2) \rho_{app}} = \frac{\alpha_{solid} N_A}{3 \epsilon_0 M_{solid}} \tag{3.33}
\]

The assumption of point charges is valid only for ideal ionic solids in which the ions show no overlap of their electron distribution. To overcome this shortcoming Marler suggests a general refractivity formula which takes into consideration an overlap field of near-neighbour interactions.

\[
\frac{n^2 - 1}{(4 \pi + b (n^2 - 1)) \rho_{app}} = \frac{\alpha_{solid} N_A}{4 \pi \epsilon_0 M_{solid}} \tag{3.34}
\]

with the electronic overlap parameter

\[
b = \frac{4 \pi}{3} - \gamma \tag{3.35}
\]

where \(\gamma\) is a material constant resulting from the overlap field. Equation (3.32e) includes as special cases the Clausius-Mosotti formula for \(b = \frac{4 \pi}{3}\) if there is no overlap field and the Newton-Drude equation for \(b = 0\) if the overlap field compensates for the Lorentz field exactly.

In this study the Clausius-Mosotti equation is used for further investigations because by applying this approach the refractive index of structures like aluminosilicates can be calculated a priori from knowledge on the properties of the solid. Therefore, the theory of Clausius-Mosotti will be explained in more detail.

**3.3.5.1. The Clausius-Mosotti equation**

The electrical field \(\vec{E}\) can be expressed by the force which results from a small point charge in this field. The field intensity \(\vec{E}\) is a vector in direction of the force vector \(\vec{F}\), the charge \(q\) is a scalar quantity [95]. It is
\[ \vec{E} = \frac{\vec{F}}{q} \]  

(3.36)

For the displacement of a charge \( q \) in a homogenous field between two charged parallel plates of distance \( d \) and voltage \( U \) the work

\[ W = F d = U I t = U q \]  

(3.37)

is necessary where \( t \) is the time and \( I \) the current. With equation (3.36) it follows

\[ E = \frac{U}{d} \]  

(3.38)

The charges bonded on a loaded matter (e.g. the plates of a condenser) determine the quantity of the field intensity. The charge density \( \sigma \) is defined as the ratio of the matter’s charge \( q \) to its loaded surface \( S \) with

\[ \sigma = \frac{q}{S} = \varepsilon_0 E \]  

(3.39)

where \( \varepsilon_0 \) denotes the permittivity of free space, \( \varepsilon_0 = 8.85 \times 10^{-12} \text{ C/(V*m)} \). If an electrical nonconducting material is inserted into the electrical field the charge density rises with a factor \( \varepsilon_r \) which is the relative permittivity. It is then

\[ \sigma = \varepsilon_r \varepsilon_0 E \]  

(3.40)

The difference of the charge densities after and before inserting the so-called dielectric into the electrical field is the electrical polarisation \( P \) with

\[ P = \varepsilon_r \varepsilon_0 E - \varepsilon_0 E = \varepsilon_0 E (\varepsilon_r - 1) \]  

(3.41)
Through the polarisation the charges of the dielectric are separated with the results of a dipole moment $\mu$. With the number density $\rho_j$ of dipole moments in an examined volume element the polarisation also can be written as [94]

$$P = \rho_j \mu$$ \hspace{1cm} (3.42)

It is common knowledge that the number density $\rho_j$ of particles in a volume element can be calculated via

$$\rho_j = \frac{N_A \rho_{app}}{M}$$ \hspace{1cm} (3.43)

where $N_A$ is the Avogadro constant, $M$ the molar mass and $\rho$ the density. Inserted into equation (3.42) a relation between a molecular property, the dipole moment, and a macroscopic measurable quantity, the polarisation $P$ is obtained with

$$P = \frac{N_A \rho_{app}}{M} \mu$$ \hspace{1cm} (3.44)

The induced free surface charges are the consequence of three processes in the molecular area which occur in presence of an outer electrical field. The polarisation is then the sum of three different parts with

$$P = P_e + P_a + P_\mu$$ \hspace{1cm} (3.45)

where $P_e$ is the electronic polarisation, $P_a$ the atomic polarisation and $P_\mu$ the orientational polarisation. The electronic polarisation is evident in all atoms and molecules. It is based on the fact that the charge centre of core frame and electronic shell is dispersed through the outer electrical field in different directions. The atomic polarisation occurs at all polar molecules and is based on the changes of bonding distances and bonding angles. These two polarisation parts are combined under the term of displacement polarisation. The induced dipole moment is the consequence of it. The orientational polarisation occurs only at polar molecules with permanent dipole
moment. It is based on the partial arrangement of the molecular dipole moments in direction of the electrical field.

In the following a molecule is considered which is not an electrical dipole in an electrical field. Due to displacement of its charge centre it gets an induced dipole $\mu_{\text{ind}}$ which is proportional to the electrical field intensity $E$ with

$$\mu_{\text{ind}} = \alpha E$$  \hspace{1cm} (3.46)

where $\alpha$ is the molecular polarisability in $(C^2 m^2)/J$, a measure for the ability of the molecule to deform. With equation (3.44) it follows that

$$P = \frac{N_A P_{\text{app}}}{M} \alpha E$$  \hspace{1cm} (3.47)

If the medium consists of polar molecules the molecules are influenced not only by the outer electrical field $E_{\text{outer}}$ but also by an inner electrical field $E_{\text{inner}}$. Lorenz [128] and Lorentz [129] independently derived the overall field $E$ inside a spherical volume element according to

$$E = E_{\text{outer}} + E_{\text{inner}} = E_{\text{electrical}} + \frac{1}{3} \frac{P}{\varepsilon_0}$$  \hspace{1cm} (3.48)

With equation (3.47) it follows that

$$P = \frac{N_A P_{\text{app}}}{M} \alpha \left( E_{\text{electrical}} + \frac{1}{3} \frac{P}{\varepsilon_0} \right)$$  \hspace{1cm} (3.49)

With equation (3.41) we obtain

$$P = \frac{N_A P_{\text{app}}}{M} \alpha \left( \frac{P}{\varepsilon_0 (\varepsilon_r - 1)} + \frac{1}{3} \frac{P}{\varepsilon_0} \right)$$  \hspace{1cm} (3.50)
This equation is independent of the polarisation and can be rewritten as the Clausius-Mosotti equation:

\[
\frac{N_A \alpha}{3 \varepsilon_0} = \frac{M}{\rho_{app}} \left( \frac{\varepsilon_r - 1}{\varepsilon_r + 2} \right) \tag{3.51}
\]

With this relationship and the relative permittivity the polarisability of the material can be calculated or vice versa. The aim of the next Section is to derive a new relationship in order to calculate the refractive index of solids like zeolites. It is based on the theory of Maxwell.

### 3.3.5.2. Refractive index of zeolites

Electromagnetic waves are generated when charged particles accelerate. Their existence was predicted in 1865 by James Clerk Maxwell on theoretical grounds. They were first produced and studied in 1888 by Heinrich Rudolf Hertz. The Maxwell equations are a group of equations which centralise the basic laws of electric and magnetic appearances to one package. Only the last of four equations has been derived by Maxwell but he was the first to draw the right conclusions from them [96].

He found that the electromagnetic waves spread out with a velocity:

\[
c_0 = \frac{1}{\sqrt{\varepsilon_0 \mu_0}} \tag{3.52}
\]

With equation (3.52) Maxwell has unified the permittivity of free space \(\varepsilon_0\), the permeability of free space \(\mu_0\), and the speed of light in vacuum, which was found to be \(c_0\).

In the general case the spreading speed of the electromagnetic wave in a medium is:

\[
w = \frac{1}{\sqrt{\varepsilon \mu}} \tag{3.53}
\]
where \( \varepsilon \) is the permittivity of the medium and \( \mu \) the permeability of it. It is

\[
\varepsilon = \varepsilon_r \varepsilon_0 \quad \text{and} \quad \mu = \mu_r \mu_0 \tag{3.54}
\]

where \( \varepsilon_r \) and \( \mu_r \) are the relative permittivity and the relative permeability of the medium respectively. With equation (3.53) it follows:

\[
w = \frac{1}{\sqrt{\varepsilon_r \varepsilon_0 \mu_r \mu_0}} \tag{3.56}
\]

Especially for visible light \( \mu_r \) can only approximately be 1 because matters with a big \( \mu_r \), e.g. ferromagnetics like iron and nickel, are intransparent. Zeolites are assumed in this work not to be magnetic. With equation (3.52) and the above assumption it follows:

\[
w = c_0 \frac{1}{\sqrt{\varepsilon_r}} \tag{3.57}
\]

The relation of this equation with the refractive index \( n \) can be found by using the law of Snell. Willebrord Snell van Royen, a Dutch mathematician and geodesist, discovered in the early 1600s the law of refraction. If an electromagnetic wave trespasses the frontier of two media it changes with its velocity also its spreading direction. The wave will be refracted like in figure 3.7.

The law of refraction predicats that the ratio of the angles \( \alpha \) and \( \beta \) are equal to the ratio of the wave velocities in the different media, therefore

\[
\frac{\sin(\alpha)}{\sin(\beta)} = \frac{w_1}{w_2} = n \tag{3.58}
\]
Figure 3.7: Snell’s law of refraction.

This ratio is defined as the refractive index \( n \). With equation (3.57) and \( w_1 = c_0 \) in this special case and with \( w_2 \) as the wave velocity in the medium, it is

\[
n = \frac{w_1}{w_2} = \frac{c_0}{w} = \sqrt{\varepsilon_r} \quad (3.59)
\]

known as the relation of Maxwell. If the Maxwell equation

\[
\varepsilon_r = n^2 \quad (3.60)
\]

is inserted in the Clausius-Mosotti equation (3.51) the Lorenz-Lorentz relationship between the refractive index \( n \) of a medium and the polarisability \( \alpha \) is obtained:

\[
\frac{N_A \alpha}{3 \varepsilon_0} = \frac{M}{\rho_{app}} \frac{(n^2 - 1)}{(n^2 + 2)} \quad (3.61)
\]

The aim of this Section is to derive a formulation to calculate the refractive index of solids like zeolites. Therefore, the polarisability of the adsorbent or the left side of equation (3.61) has to be known. This left side is also defined as the molar refractivity \( R_m \) with

\[
R_m = \frac{N_A \alpha}{3 \varepsilon_0} = \frac{M}{\rho_{app}} \frac{(n^2 - 1)}{(n^2 + 2)} \quad (3.62)
\]

where \( R_m \) is in \( m^3/mol \) [98]. The refractive index of the solid is then
The molar refraction of a molecule with the structure $A_{x_A}B_{x_B}$ is

$$ R_m = x_A R_{m,A} + x_B R_{m,B} $$

(3.64)

where $x_A$ and $x_B$ are the stoichiometrical coefficients and $R_{m,A}$ and $R_{m,B}$ the ionic molar refractions of the matters A and B, respectively. In general it is

$$ R_m = \sum_i x_i R_{m,i} $$

(3.65)

The ionic molar refractivities $R_{m,i}$ can be calculated via equation (3.62) if the ionic polarisabilities $\alpha_i$ are known. It is therefore

$$ R_{m,i} = \frac{N_A}{3\epsilon_0} \alpha_i $$

(3.66)

In the Handbook of Chemistry and Physics [6] the polarisability volumes $\alpha_i$ are tabulated for the interesting ions of aluminosilicates. The polarisability $\alpha_i$ is related to the polarisability volume $\alpha_i'$ via

$$ \alpha_i = 4\pi \epsilon_0 \alpha_i' $$

(3.67)

In table 3.6 the interesting properties are listed. As an example the refractive index of MS5A is calculated.

MS5A has the chemical structure Ca$_5$Na$_2$(AlO$_2$)$_{12}$(SiO$_2$)$_{12}$. Its molar mass $M$ is calculated due to the molar masses of the involved matters which are listed in table 3.7 with

$$ M = \sum_i x_i M_i $$

(3.68)

where $M$ and $M_i$ is in kg/mol and $x_i$ the stoichiometrical coefficients. For MS5A it is

$$ M_{MS5A} = 1.68 \frac{kg}{mol} $$

(3.69)

Sievers [37] measured for MS5A a pellet density of

$$ \rho_{app,MS5A} = 1150 \frac{kg}{m^3} $$

(3.70)

The molar refractivity of MS5A is calculated with the values of the ionic molar refractivites of table 3.6 with

$$R_{m,MS5A} = 4.79 \cdot 10^{-4} \frac{m^3}{mol} \quad (3.71)$$

Finally the refractive index of MS5A is

$$n_{MS5A} = 1.57 \quad (3.72)$$

Direct measurements for zeolites were only found for MS4A and silicalite-1. Nevertheless the proposed way of refractive index calculation is very straightforward and independent of experimental work. It is an important parameter for the calculation of *Hamaker* constants, e.g. for aluminosilicates, as shown in the next Section.
3.3.6. Hamaker constant

For the characterisation of solid materials their interaction potentials with other solids or fluids are of strong interest. One of the most important parameters for describing the disperse energies of a given system is the so-called Hamaker constant of the solid. This constant is also eminent for the calculation of adsorption equilibria of gases on energetically homogeneous and heterogeneous surfaces.

Hamaker constants of organics (solids and liquids) in air have magnitudes of $(6 \pm 1) \times 10^{-20}$ J and are reported to be lower than those of inorganic salts $((9 \pm 3) \times 10^{-20}$ J), which are again lower than those of metal oxides $((13 \pm 4) \times 10^{-20}$ J) [41]. Götzinger [49] reports in table 3.8 constants of several inorganic and organic matters.

Van der Hoeven [41] reports two methods for the estimation of Hamaker constants. The first one is based on the macroscopic theory of Lifshitz. It requires the knowledge of the absorption spectrum and the dispersion, i.e. the refractive index $n(\omega)$ and the dielectric permittivity $\varepsilon(\omega)$ as a function of frequency. The other method is the Hamaker-de Boer microscopic summation approach. This method is based on the subdivision of the inorganic solid molecules into atoms, which all have an average composition and polarisability, identical to that of the solid molecule. The method requires, apart from the refractive indexes and dielectric constants, the molar masses...
and the specific densities of the materials involved. A brief description of these two methods and their theories is given in the next sections.

3.3.6.1. Macroscopic approach of Lifshitz

_Hamaker_ [75] experienced in 1937 the existence of adhesive forces between small particles. He ascribed this adhesion for a large part to _London van-der-Waals_ forces. In his theory the energy of interaction between two particles containing \( \rho_{j,\text{at}} \) atoms per m\(^3\) is given by

\[
E = -\int_{v_1} \int_{v_2} \rho_{j,\text{at}}^2 \beta \frac{dV}{r^6} \quad \text{(3.73)}
\]

where \( dv_1, dv_2, V_1 \) and \( V_2 \) designate volume elements and total volumes of the two particles, respectively, \( r \) denotes the distance between \( dv_1 \) and \( dv_2 \) in m and \( \beta \) is the _London van-der-Waals_ constant in J*m\(^6\).

The mutual energy of two spheres of diameters \( D_1 \) and \( D_2 \), with the distance \( d \) according to figure 3.8 and containing \( \rho_{1,\text{at}} \) and \( \rho_{2,\text{at}} \) atoms per m\(^3\) which interact with an energy \( \frac{\beta}{r^6} \) is according to _Hamaker_ (see Figure 3.8)

\[
E = -\frac{Ha}{12} \left( \frac{y_1}{x_1^2 + x_1 y_1 + x_i} + \frac{y_1}{x_1^2 + x_1 y_1 + x_i + y_i} + 2 \ln \left\{ \frac{x_1^2 + x_1 y_1 + x_i}{x_1^2 + x_1 y_1 + x_i + y_i} \right\} \right) \quad \text{(3.74)}
\]

where the variables are defined as

\[ Ha = \pi^2 \rho_{1,\text{at}} \rho_{2,\text{at}} \beta , \quad \text{(3.75)} \]

\[ x_i = \frac{d}{D_i} \quad \text{and} \]

\[ \text{(3.76)} \]
Figure 3.8: Two interacting spheres.

The constant $H_a$ is also known as the Hamaker constant and is defined for like particles with the same atom density $\rho_{j,at}$ as

$$H_a = \pi^2 \rho_{j,at}^2 \beta$$  \hspace{1cm} (3.78)

When $x_1 \ll 1$ or $d \rightarrow 0$ equation (3.74) is approximated by

$$E = -H_a \frac{1}{12} \frac{D_2 D_1}{d(D_2 + D_1)}$$  \hspace{1cm} (3.79)

Ackler et al. [76] calculated the Hamaker constant of muscovite mica, Al$_2$O$_3$, SiO$_2$, Si$_3$N$_4$ and rutile TiO$_2$ from Lifshitz theory. He compared these constants to values calculated from physical properties using the Tabor-Winterton approximation.

Lifshitz developed a theory for the nonretarded case where the interparticle separations are small enough that the interactions between dipoles is considered instantaneous. The van-der-Waals interaction is the result of fluctuations in the electromagnetic field between two macroscopic bodies, modified by the separating media, where the interaction can be referred to the standing waves which only occur at certain frequencies. Hence, the van-der-Waals interaction and, thus, the associated Hamaker constants can be estimated from the knowledge of the frequency dependent dielectric properties of the interacting materials together with
the intervening medium and the geometry of the bodies. The accuracy of the estimated *Hamaker* constants is directly related to the precision and accuracy of the dielectric spectra and the mathematical representation of this data [77].

The dielectric properties of materials are commonly represented by the frequency dependent dielectric response function

\[
\varepsilon(\omega) = \varepsilon'(\omega) + i\varepsilon''(\omega)
\]

(3.80)

which is a complex function here, \(\varepsilon'(\omega)\) is the real part and \(\varepsilon''(\omega)\) the imaginary part. For a static applied field (\(\omega = 0\)), non-conductor materials are characterised by \(\varepsilon''(0) = 0\), hence \(\varepsilon'(0) = \varepsilon(0)\) which is the static dielectric constant. For this case the real part of the dielectric response is directly related to the refractive index \(n\) through

\[
\varepsilon(0) = \varepsilon'(0) = n^2(0)
\]

(3.81)

Dielectric data can be obtained with a number of methods including capacitance bridge, optical reflectance and electron loss spectrometry. Most of these techniques yield only one of the components of the complex dielectric response function which often necessitate the transformation from the real to the imaginary component or vice versa. Such a transformation can be performed using the *Kramers-Kronig* relations, one of them defined as

\[
\varepsilon'(\omega) = 1 + \frac{2}{\pi} \int_0^\infty \frac{\varepsilon''(\omega)}{x_1^2 - \omega^2} dx_1
\]

(3.82)

However, since the *Kramers-Kronig* relation is formally correct only when \(\varepsilon''(\omega)\) is known in the entire frequency range, \(0 < \omega < \infty\), this procedure is applicable. *Nimhan* and *Parsegian* showed that by constructing an imaginary dielectric response function, \(\varepsilon(i\xi_m)\), a much simpler dielectric representation could be used for the purpose of calculating *Hamaker* constants. In the study of *Bergström* [77] \(\varepsilon(i\xi_m)\) is represented for most of the inorganic materials by one UV and IR relaxation through
where each material is characterised by four parameters; $C_{IR}$ and $C_{UV}$ are the absorption strengths in the IR and UV range, respectively, and $\omega_{IR}$ and $\omega_{UV}$ represent the characteristic absorption frequencies in the IR and UV range, respectively. It is

$$C_j = \frac{2 f_j}{\pi \omega_j}, \quad j = \text{IR, UV}$$

(3.84)

where $f_j$ is the oscillator strength and $\omega_j$ is the relaxation frequency of the absorption band. Now, the non-retarded Hamaker constant of two particles 1 and 2 in medium 3 can be derived from the integral

$$H_{a_{132}} = \frac{3kT}{2} \sum_{\Delta m=0}^{\infty} \int_{0}^{\infty} x_1 \ln(1 - \Delta 13 \Delta 23 \exp(-x_1)) dx_1$$

(3.85)

This integral can be solved analytically to yield

$$H_{a_{132}} = \frac{3kT}{2} \sum_{m=0}^{\infty} \sum_{n=1}^{\infty} \frac{(\Delta 13 \Delta 23)^{m}}{s^{3}}$$

(3.86)

where $k$ is the Boltzmann constant and $T$ the temperature in K and with the differences in dielectric response, $\Delta kl$, defined as

$$\Delta kl = \frac{\varepsilon_k(i\xi_m) - \varepsilon_j(i\xi_m)}{\varepsilon_k(i\xi_m) + \varepsilon_j(i\xi_m)}$$

(3.87)

Bergström [77] used simplified approximations by only retaining a single UV relaxation to represent the dielectric response of each material. His simplifications have been motivated by the important role of the ultraviolet relaxations on the magnitude of the disperse interactions. With such a simple dielectric representation
each material is fully described by three parameters, \( \varepsilon(0) \), the characteristic frequency in the ultraviolet, \( \omega_{\text{UV}} \), and the low-frequency limit of refractive index in the visible UV range, \( n_0 \) (since \( C_{UV} = n_{vis}^2 - 1 \)). For example, he calculated the Hamaker constant \( H_{a_{131}} \) for two identical materials 1, interacting across a medium 3, by using (3.36), neglecting all summation terms \( s > 1 \), converting the summation over \( m \) to an integral for \( n > 1 \), and finally setting \( \omega_1 = \omega_2 = \omega \). This results in

\[
H_{a_{131}} = \frac{3kT}{4} \left( \frac{\varepsilon_1(0) - \varepsilon_3(0)}{\varepsilon_1(0) + \varepsilon_3(0)} \right)^2 + \frac{3h\omega}{32\pi\sqrt{2}} \left( \frac{n_1^2 - n_3^2}{n_1^2 + n_3^2} \right)^2
\]

(3.88)

Both authors (Bergström and Ackler) compared their data with the Tabor-Winterton approximation for the Hamaker constant. Beside the above simplification of ignoring contributions from vibrations in the infrared a second approximation is made that the absorption in the UV occurs within a narrow frequency range. It follows

\[
H_{a_{131}} = \frac{3\pi h\nu_e}{8\sqrt{2}} \left( \frac{n_1^2 - n_3^2}{n_1^2 + n_3^2} \right)^2
\]

(3.89)

where \( h \) is the Planck’s constant and \( \nu_e \) the main electronic absorption frequency of about \( 3 \times 10^{15} \) Hz also called the plasma frequency. Recalling that \( n = \varepsilon^2 \), it is apparent that the Tabor-Winterton approximation enables the calculation of a Hamaker constant only from physical properties such as the refractive index or the dielectric constant of the materials of interest and of the medium “3”.

In the case of two interacting identical macrobodies (index1) in vacuum Israelachvili derived the following expression which allows to approximate the Hamaker constant [21, 98]:

\[
H_{a_{11}} = \frac{3kT}{4} \left( \frac{\varepsilon_1(0) - 1}{\varepsilon_1(0) + 2} \right)^2 + \frac{3h\nu_e}{16\sqrt{2}} \left( \frac{n_1^2 - 1}{n_1^2 + 1} \right)^2
\]

(3.90)
In this equation, instead of integration over the whole frequency area, $\varepsilon(\omega)$ and $n(\omega)$ in the original equations of Lifshitz are replaced by two static values, one at low frequencies, i.e. the static dielectric constant $\varepsilon$, and one at high frequency, i.e. the refractive index $n$ of the medium in visible light.

In this macroscopic approach the static dielectric constant is not known in many cases or must be measured in a complex way. Considering the large differences in chemical compositions, it is unlikely that inorganic matters all have the same $\nu_e$ value of $3 \cdot 10^{15}$ s$^{-1}$. Nevertheless Israelachvili has shown that the results of equation (3.90) are accurate within a few percent when compared with the results of exact computations.

In the next Section the Hamaker – de Boer microscopic approach is introduced which is used in this work for the derivation of the London interaction forces.

### 3.3.6.2. Microscopic approach of Hamaker – de Boer

The Hamaker – de Boer microscopic approach is based on the equation

$$Ha = \pi^2 \rho_{j,\text{at}}^2 \beta$$  \hspace{1cm} (3.78)

where $\rho_{j,\text{at}}$ is the is the number density of solid atoms in $1/m^3$ and $\beta$ the London constant in $J*m^6$ [75]. This approach is strictly speaking valid only for monoatomic solids. If the Hamaker constant of multiatomic solids is calculated their chemical structure has to be considered. The proposed route is based on a subdivision of the solid molecule into atoms, which all have a mean concentration and polarisability. The Hamaker constant is then calculated due to these mean polarisabilities. A second assumption is that only the valence electrons of these atoms contribute to the disperse interaction potential. So the average atoms are all bonded by semi-polar bonds and only the bond-forming electrons contribute to the higher energetic waves.

The Hamaker constant for multiatomic solid molecules is then
\[ Ha = \pi^2 \rho_{j,at}^2 \bar{\beta} \]  

(3.91)

where \( \rho_{j,at} \) is the number density of solid atoms and \( \bar{\beta} \) the London constant. The number density can be calculated via

\[ \rho_{j,at} = n_a \frac{N_A \rho_{app}}{M} \]  

(3.92)

where \( n_a \) is the number of atoms in the molecule. \( M \) denotes the relative atomic mass related to the same solid molecule with which the number of atoms is calculated. In the following the zeolite MS5A with the chemical structure \( \text{Ca}_5\text{Na}_2((\text{AlO}_2)_{12}(\text{SiO}_2)_{12}) \) is examined. Its molecular mass is given in equation (3.69). The overall number of atoms \( n_a \) in this molecule is

\[ n_{a,MS5A} = 79 \]  

(3.93)

With the density in equation (3.70)

\[ \rho_{MS5A,at} = 3.27 \cdot 10^{28} \, \frac{1}{m^3} \]  

(3.94)

is obtained.

The magnitude of this number density of atoms for zeolite MS5A is comparable to many materials, for example silicon has a number density of \( 5.0 \cdot 10^{28} \, \frac{1}{m^3} \) and \( \text{SiO}_2 \) a number density of \( 2.2 \cdot 10^{28} \, \frac{1}{m^3} \) [101].

In 1931 Slater and Kirkwood [100] derived an equation for the calculation of the London constant. Van-der-Hoeven [41] modified this equation by introducing an atomic polarisability. The London constant for macro bodies like zeolites can be calculated by
\[
\bar{\beta} = \frac{3}{4} \sqrt{s} \hbar \nu_0 \left( \frac{\alpha}{4\pi \varepsilon_0} \right)^2
\]  

(3.95)

The letter \( s \) represents the number of electron bondings per atom. It is obtained simply from the summation of the single and double bond forming electrons involved in atomic bonding, divided by the number of atoms in the molecule. The parameter \( s \) is only reasonable for the calculation of the Hamaker constant and London dispersion potential, respectively. Later this potential will be introduced as the induced dipole – induced dipole interaction energy.

For example, for zeolite MS5A (Ca₅Na₂((AlO₂)₁₂(SiO₂)₁₂)) the total number of atoms in the molecule is 79. The number of valence electrons is for calcium 5*2 = 10, for sodium 2*1 = 2, for aluminium 12*3 = 36, for silicon 12*4 = 48 and for oxygen 48*6 = 288, altogether 384 valence electrons. The number of electron bondings is then 192. It follows for \( s \) that

\[
{s_{\text{MS5A}}} = \frac{192}{79} = 2.43
\]  

(3.96)

The polarisability of the solid atoms can be calculated from the refractive index using the *Lorenz-Lorentz* equation

\[
\alpha = 4\pi \varepsilon_0 \frac{M}{n_u} \frac{M}{4\pi N_A \rho} \left( \frac{n^2 - 1}{n^2 + 2} \right) = \varepsilon_0 \frac{3M}{n_u N_A \rho} \left( \frac{n^2 - 1}{n^2 + 2} \right)
\]  

(3.97)

with the already known parameters.

The variable \( \nu_0 \) is the frequency of the electron in the ground state in 1/s. It is

\[
\nu_0 = \frac{e}{2\pi \sqrt{m_e} \sqrt{\alpha}}
\]  

(3.98)
where $e$ is the charge of an electron ($e = 1.60 \times 10^{-19}$ C) and $m_e$ the mass of an electron ($m_e = 9.11 \times 10^{-31}$ kg). With known or calculated values of the refractive index $n$, the apparent density $\rho$, the molar mass $M$ and the chemical structure of the solid the *Hamaker* constant for zeolites can be calculated. For MS5A it is:

$$H_{a_{MS5A}} = 7.66 \times 10^{-20} \text{ J}$$  \hfill (3.99)

### 3.4. Adsorption isotherms

In this study single-component equilibria of gases or vapours with microporous solids are examined. The context does not cover phenomena like chemisorption, hydrogen bonding, steric or formselective effects. Attention is payed only to physisorption only, the adsorptive gas molecules are physically bonded to the microporous surface via potential forces. In this Section the existing types and common descriptions of adsorption isotherms are discussed which are used in this work for different purposes. E.g. measuring the specific surface according to the BET isotherm, calculating Henry coefficients by means of *Langmuir* and *Toth* isotherms.

#### 3.4.1. Types of isotherms

The first classification of physical adsorption isotherms was presented by *Brunauer et al.* [78]. In 1985 the IUPAC Commission on Colloid and Surface Chemistry proposed modifications of this classification by adding a sixth type, the stepped isotherm, to the original five types of *Brunauer et al.*. Type I (the *Langmuir* isotherm) is typical for microporous adsorbents (activated carbons, zeolites). The next two are typical for nonporous materials with strong (type II) and weak (type III) fluid-surface forces. Types IV and V are characteristic for mesoporous materials when capillary condensation occurs (these types exhibit hysteresis loop). Type VI occurs for materials with relatively strong fluid-surface forces, usually when the temperature is near the melting point of the adsorbed gas [79]. Figure 3.9 shows the principle types of adsorption isotherms regarding to IUPAC classification.
Figure 3.9: Principle types of adsorption isotherms regarding to IUPAC classification.

Nevertheless, the classification of adsorption isotherms in several types is not helpful for the understanding of the decisive physical processes. Also the evaluation of the isotherm types as advantageous or disadvantageous is ambivalent, because an advantageous form for adsorption is at the same time a disadvantageous form for desorption [24]. This work deals mainly with isotherms of type I.
**3.4.2. Langmuir isotherm**

Irving Langmuir developed 1918 a quantitative theory of monolayer adsorption which is simple and ingenious at the same time [80]. Figure 3.10 shows the principle basis of the *Langmuir* model. The assumptions are [82]:

- The molecules are adsorbed on well-defined and localised places.
- Each adsorption place can bind only one adsorptive molecule.
- All adsorption places are energetically equivalent.
- There are no interactions between adsorbed molecules.

![Figure 3.10: Principle of the *Langmuir* model.](image)

For the attachment of molecules with solid surfaces the following reaction is essential:

\[
\Delta_f + G \leftrightarrow OP
\]

The adjustment of a sorption equilibrium leads to the equilibrium constant \( K_L \), which is the ratio of the concentration of free gas molecules [G], the concentration of free places \( [\Delta_f] \) and the concentration of occupied places [OP]:

\[
K_L = \frac{[OP]}{[G][\Delta_f]}
\]
\[ K_L = \frac{[OP]}{[G][\Delta_f]} \]  

(3.101)

K_L is called the *Langmuir* constant and has the dimension 1/pressure because the concentration of free gas molecules [G] is equivalent to the partial pressure \( p \) of the adsorptive. The sum of the concentration of free places and occupied places is the maximum available concentration of sorption places [SP]. It is

\[ [SP] = [OP] + [\Delta_f] \]  

(3.102)

and it follows with

\[ [\Delta_f] = [SP] - [OP] \]  

(3.103)

for the Langmuir constant in equation (3.101)

\[ K_L = \frac{[OP]}{[G][SP] - [OP]} \]  

(3.104)

After resolution to the concentration of occupied places it follows:

\[ [OP] = [SP] \frac{K_L[G]}{1 + K_L[G]} \]  

(3.105)

The concentrations of occupied and maximum available sorption places are equivalent to the loading \( n \) and the maximum available loading \( n_{\text{mon}} \) of gas molecules on the solid surface. So the *Langmuir* isotherm for monolayer loadings can be immediately written to

\[ n = n_{\text{mon}} \frac{K_L p}{1 + K_L p} \]  

(3.106)
For very low pressures $K_L p$ becomes negligible compared to unity, so that as a first approximation the Henry isotherm is obtained:

$$n = n_{\text{mon}} K_L p$$

(3.107)

The product of the constants $n_{\text{mon}} K_L$ is equal to the Henry coefficient $H_e$. These constants are adjustable coefficients to adsorption data. With a linearised form the Langmuir coefficients can be derived via a graph with $p$ as the x axis and $p/n$ as the y axis. It is

$$\frac{p}{n} = \frac{1}{n_{\text{mon}} K_L} + \frac{1}{n_{\text{mon}}} p$$

(3.108)

The Henry coefficient is then indirect proportional to the intercept point $L_i$:

$$H_e = \frac{1}{L_i} = \frac{1}{\left( n_{\text{mon}} K_L \right)}$$

(3.109)

The Langmuir isotherm can also be derived from statistical thermodynamics and by using Gibb’s isotherm [81].

### 3.4.3. BET isotherm

The BET isotherm is eminent for the determination of the specific surface of adsorbents. Therefore, the isotherm is derived theoretically in this Section. With the help of a few simplifying assumptions it is possible to carry out an isotherm derivation for multimolecular layers that is similar to Langmuir’s derivation for monolayers [62]. Brunauer, Emmett and Teller look at the surface layers $s_i$ covered by only $i$ layers of adsorbed molecules. Using Langmuir’s equation for monolayer adsorption they derive the general equation

$$a_i p s_{i-1} = b_i s_i \exp \left( \frac{-H_i}{RT_{\text{adv}}} \right)$$

(3.110)
where $p$ is the pressure in Pa, $H_i$ the specific heat of the $i$-th layer in J/mol, $a_i$ a mole rate constant of layer $i$ in mol/(m$^2$s*Pa), $b_i$ a mole rate constant of layer $i$ in mol/(m$^2$s) and $s_i$ the surface of the molecule layer $i$ in m$^2$. Equation (3.110) means that the rate of condensation on top of the layer $i-1$ is equal to the rate of evaporation of the $i$-th layer. Brunauer et al. proposed the following points:

- The specific heat of the first layer is the heat of adsorption $H_{\text{ads}}$.
- The specific heat of the $i$-th layer is the heat of liquefaction $H_L$ with

$$H_1 = H_2 = \ldots H_i = H_L$$

(3.101)

This is equivalent to saying that the evaporation-condensation properties of the molecules in the second and higher adsorbed layers are the same as those of the liquid state. This means also that

$$\frac{b_2}{a_2} = \frac{b_3}{a_3} = \ldots \frac{b_i}{a_i} = g$$

(3.102)

where $g$ is an appropriate constant in Pa.
- At equilibrium the surface layers $s_i$ remain constant.

The total surface $S$ is given by

$$S = \sum_{i=0}^{\infty} s_i$$

(3.103)

and the total volume adsorbed is

$$V_G = v_0 \sum_{i=0}^{\infty} i s_i$$

(3.104)

where $v_0$ is the volume of gas adsorbed on one square meter of the adsorbent surface when it is covered with a complete monolayer of adsorbed gas. It follows that
\[
\frac{V_G}{S v_0} = \frac{V_G}{V_{G,\text{mon}}} = \sum_{i=0}^{\infty} \frac{i s_i}{s_i}
\]

(3.105)

where \(V_{G,\text{mon}}\) is the volume of gas adsorbed when the entire adsorbent surface is covered with a complete monolayer. One can express now \(s_1, s_2, \ldots, s_i\) in terms of \(s_0\) whereas

\[
s_1 = y s_0 \quad \text{where} \quad y = \frac{a_i}{b_i} p \exp \left( \frac{H_{\text{ads}}}{\mathcal{R} T_{\text{ads}}} \right)
\]

(3.106)

\[
s_2 = \varphi s_1 \quad \text{where} \quad \varphi = \frac{p}{g} \exp \left( \frac{H_2}{\mathcal{R} T_{\text{ads}}} \right)
\]

(3.107)

\[
s_i = \varphi s_{i-1} = \varphi^{i-1} s_1 = y \varphi^{i-1} s_0 = c \varphi^{i} s_0 \quad \text{where} \quad c = \frac{y}{\varphi} \frac{a_i g}{b_i} \exp \left( \frac{H_{\text{ads}} - H_2}{\mathcal{R} T_{\text{ads}}} \right)
\]

(3.108)

The variable \(\varphi\) can also be understood as the relative saturation, the ratio of the pressure of the gas to its saturation pressure. The variable \(c\) is the well known BET constant.

Substituting (3.106), (3.107) and (3.108) into equation (3.105) yields

\[
\frac{V_G}{V_{G,\text{mon}}} = \frac{c s_0 \sum_{i=1}^{\infty} i \varphi^i}{s_0 \left( 1 + c \sum_{i=1}^{\infty} \varphi^i \right)}
\]

(3.109)

If the number of the adsorbed layers cannot exceed a maximum number \(n\), then the summation of the two series in equation (3.109) is to be carried out to \(n\) terms only, and not to infinity. It follows then

\[
\frac{V_G}{V_{G,\text{mon}}} = \frac{c \varphi}{(1 - \varphi)} \frac{1 - (n + 1) \varphi^n + n \varphi^{n+1}}{1 + (c - 1) \varphi - c \varphi^{n+1}}
\]

(3.110)
which is the well known general BET isotherm. For the determination of the solid surface $S_{BET}$ the summation of the two series has to be carried out to infinity. The denominator sum can be represented as the sum of an infinite geometric progression

$$\sum_{i=1}^{\infty} \varphi^i = \frac{\varphi}{1-\varphi}$$

(3.111)

and the numerator sum can be expressed also in the same way as

$$\sum_{i=1}^{\infty} i\varphi^i = \frac{\varphi}{(1-\varphi)^2}$$

(3.112)

It follows therefore that

$$\frac{V_G}{V_{G,mon}} = \frac{c\varphi}{(1-\varphi)(1-\varphi+c\varphi)}$$

(3.113)

With

$$\varphi = \frac{p}{p^0}$$

(3.114)

equation (3.2) for the determination of the solid surface $S_{BET}$ is obtained.

### 3.4.4. Toth isotherm

One of the assumptions of Langmuir is the energetic homogeneity of the adsorbent surface. This assumption is not always valid. Toth also tried to take into account the energetic heterogeneity in his adsorption equilibrium modell [83]. The basis of his theory is the dividing of the surface in a huge number of homogeneous fields with very small areas. With the partial loading
he wrote in a first step the Langmuir equation (3.106) in the differential form

\[ \frac{N}{p} \frac{dp}{dN} - 1 = K_L p \]  

(3.116)

Toth introduced a differential function \( \Psi(p) \) which describes the whole energetic heterogeneous loading interval:

\[ \psi(p) = K_T p^m \]  

(3.117)

where \( 0 < m < 1 \) and \( K_T \) is the Toth constant in \( (1/\text{Pa})^m \). The backwards integration of equation (3.116) with equation (3.117) yields the Toth isotherm

\[ N = \frac{n}{n_{max}} = \frac{p}{\left( \frac{1}{K_T} + p^m \right)^{\frac{1}{m}}} \]  

(3.118)

The Henry coefficient follows at very small pressures. It is

\[ He = \lim_{p \to 0} \left( \frac{n}{p} \right) = n_{max} \left( K_T \right)^{\frac{1}{m}} \]  

(3.119)

The qualitative difference of Henry coefficient derivations via the Langmuir and Toth isotherms is discussed in Chapter 7.

3.4.5. Potential theories

The isotherms of Langmuir, Brunauer et al. and Toth are derived from equilibrium or kinetic considerations. Another possibility is the inclusion of adsorption forces or potentials in the models. In this Section classic and modern concepts of potential theories are presented.
3.4.5.1. Polanyi and Dubinin

Polanyi developed his potential theory in 1916 [84]. The assumptions made are:

- The solid concentrates the adsorbed material on its surface by means of attraction forces.
- The attraction forces are dependent on system properties and the distance of the interacting molecules.
- The attraction forces are independent of temperature.
- There is no dissolution of the adsorbed molecules in the adsorbent.
- The adsorption volume is filled by liquid adsorbate only.
- Gas phase exhibits ideal gas behaviour.
- The liquid adsorbed phase is incompressible.
- Creating a liquid surface involves negligible work.

The adsorption potential is defined by Polanyi as the isothermal compression work of a molecule with partial pressure \( p \) which transfers from the gas phase to a point in the adsorbed phase with saturation pressure \( p^0 \) with

\[
\varepsilon = \mathcal{R} T_{\text{ads}} \ln \left( \frac{p^0}{p} \right)
\]  

The later studies of Dubinin on adsorption equilibria are based on the potential theory of Polanyi. The adsorption in microporous adsorbents is understood as successive filling of the pore volume. The principle task in his theory consists of finding the distribution of the volume adsorption space, \( v \), as a function of Polanyi adsorption potential \( \varepsilon \) with

\[
v = f \left( \frac{\varepsilon}{\beta} \right)
\]
where $\beta$ is called the affinity coefficient. The forces of attraction of the molecules to the surface of the adsorbent are related to the ratio of polarisability of the vapourous molecules, therefore

$$\beta = \frac{\epsilon}{\epsilon_{\text{ref}}} = \frac{\alpha}{\alpha_{\text{ref}}}$$  \hspace{1cm} (3.122)

where $\alpha$ is the polarisability of the molecule and the index “ref” indicates the reference molecule. \textit{Dubinin} assumes that the temperature does not produce any effect on this characteristic curve $v$, each adsorbent has its own characteristic curve that describes its adsorption-force field. For adsorbents of type I, including active carbons and zeolites with extremely small micropores, the equation of the characteristic curve assumes the form

$$v = v_{\text{max}} \exp \left( -\kappa \frac{\epsilon^2}{\beta^2} \right)$$ \hspace{1cm} (3.123)

where $v_{\text{max}}$ is the limiting volume of adsorption space that equals the volume of all micropores. The parameter $\kappa$ reflects the function of distribution of volume of the pores according to sizes. This theory was tested on the basis of numerous substances. It is very successful in describing adsorption equilibria of active carbons. The advantage of this approach is that for the description of the characteristic curve only one isotherm has to be examined experimentally over a big concentration interval [82]. With equation (3.120) in equation (3.123) the isotherm of \textit{Dubinin-Raduskevich} is given by

$$\frac{v}{v_{\text{max}}} = \exp \left( -\kappa \left( \frac{R T_{\text{ads}}}{\beta} \ln \frac{P_{\text{eq}}}{p} \right)^2 \right) = \frac{n}{n_{\text{max}}}$$ \hspace{1cm} (3.124)

where the ratio of the volumes can be replaced by the ratio of the loading $n/n_{\text{max}}$ for a constant density of the adsorbed phase.

A general form of equation (3.124) was derived by \textit{Dubinin} and \textit{Astakhov} [130] with
\[
\frac{v}{v_{\text{max}}} = \exp \left( -\kappa Y \right) = \frac{n}{n_{\text{max}}} \quad 1 < Y < 3 \quad (3.125)
\]

It is not possible to transfer equation (3.124) and (3.125) to Henry’s-law in the low partial pressure interval. The postulation for the thermodynamic consistency of a isotherm description is not fulfilled. Nevertheless, for bigger concentrations the Dubinin isotherms are powerful instruments.

3.4.5.2. Monte Carlo simulations

The objective of molecular modelling systems is to predict macroscopic, experimentally observable properties by simulating the molecular motion of materials [87]. One starts with a model that describes the inter- and intra-molecular interactions and then relates this through statistical mechanics to macroscopic properties. These can range from thermodynamic properties to transport properties and to molecular arrangements.

There are two major ways to solve these problems statistically. In the first one, molecular dynamics (MD), molecules move under the influence of their own molecular forces. In micro canonical molecular dynamics, one specifies the number of molecules, the energy in the system and the volume of the system. The positions of each molecule are then calculated by solving Newton’s equation for the force \( F \), the mass \( m \) and the acceleration \( a \):

\[
F = ma \quad (3.126)
\]

From this, the desired properties can be gained as a function of position and velocity as a function of time.

Another way is the Monte Carlo simulation which is a stochastic method. In a traditional or canonical Monte Carlo simulation, the volume, the number of molecules, and the temperature of the system are specified. The Monte Carlo method uses a
random number generator to propagate molecules according to the canonical probability distribution. Translation and rotation motions are accepted or rejected according to canonical accepted rules. By examining the accepted and rejected motions, an average of them can be made in order to obtain equilibrium properties for the system of interest. The algorithm in figure 3.11 gives the steps involved in Monte Carlo simulations.

![Algorithm for Monte Carlo simulations](image)

**Figure 3.11**: Steps involved in Monte Carlo simulations.

In the grand canonical Monte Carlo (GCMC) ensemble the number of particles fluctuates while the chemical potential is constrained. This makes GCMC a natural choice for studying phase equilibrium since the chemical potential of two phases must be equal at equilibrium. Thus, GCMC uses the chemical potential as the basis for adding and removing molecules from the system. In addition, the solid phase is in contact with a vapour phase of known fugacity, which is related to the chemical potential. In GCMC the four basic motions of a particle are as follows:
- Insertion into a random position in the system.
- Deletion
- Rotation
- Translation into a new position in the system.

In their review Smit and Krishna discuss the use of modern Monte Carlo simulations in the context for simulating the properties of molecules adsorbed in zeolites [88]. They show that it is possible to use Monte Carlo simulations to obtain a reasonable estimate of an adsorption isotherm of pure hydrocarbons and their mixtures in zeolites. As in all kinds of simulation methods the restrictions of Monte Carlo simulations are the limits in calculation capacity. Also the results have to be verified with experimental data because it is only a random model and not an a priori one. Nevertheless, intensive engagement with the theme of high-performance-computing is necessary to further push this auspicious methods.

3.4.6. Isotherms based on the Hamaker energy of the solid

Maurer [26] has demonstrated that the Hamaker energy $H_a$ of the adsorbent and the critical data $p_c$ and $T_c$ of the adsorptive are basic properties in order to describe equilibrium isotherms of all gases on active carbon. Mersmann et al [27] introduced a diagram in which the initial or Henry loading is plotted versus an interaction parameter $\frac{T_c}{T_{ads}} \sqrt{\frac{2H_a}{\pi \sigma^3 p_c}}$, as can be seen in figure 3.12.

With respect to the entire isotherm in figure 3.12 the dimensionless numbers $\frac{H_e p}{n}$,

$$\frac{T_c}{T_{ads}} \left( \frac{H_a}{\sigma^3 p_c} \right)^{\frac{1}{2}}$$ and $\frac{n N_A \sigma_i^2}{S_{BET}}$ have been introduced. However, all these results are restricted either to activated carbon and unpolar zeolites like silicalite-1 or to nonpolar adsorptive molecules in the case of polar zeolites.
Figure 3.12: The initial or Henry loading plotted versus the interaction parameter [27].
4. Experimental Methods for Adsorption Measurements

There are classical and also new techniques for measuring the adsorption equilibrium of gases on microporous adsorbents. The classical procedures described in this Chapter are the volumetric [8, 37, 57] and the packing bed methods [36]. The gravimetric method is explained in Chapter 7 regarding materials and methods used in this study. Newer techniques are the zero length column [89, 90] and the concentration pulse chromatography methods [91, 92].

4.1. Volumetric method

This method is widely used in literature. The adsorption equilibrium time is shortened when a gas pump is used for forced circulation of the adsorptive. Sievers [37] utilized a circulation pump with an electro-magnetic clutch between motor and rotary slide valve to ensure the required sealing. Figure 4.1 shows a feasible scheme of the volumetric method.

First, carrier gas (H₂) is dosed to a defined mixing volume \( V_{mix} \), next a small amount of adsorptive is fed. The pressure \( p_{bef} \), the temperature \( T_{bef} \) and the molar fraction of the adsorptive \( y_{bef} \) are measured, \( y_{bef} \) with a gas chromatograph. With this data the moles of adsorptive in the mixing volume can be measured and calculated:

\[
n_{bef} = \frac{y_{bef} \, p_{bef} \, V_{mix}}{Z_{bef} \, \mathbb{R} \, T_{ads}} \tag{4.1}
\]

The compressibility factor \( Z_{bef} \) can be calculated via the method of Redlich-Kwong-Soave which needs only critical data of pure substances. For adsorption the volume and also the adsorbent is switched on. The overall volume is \( V_{ads} \). The pressure \( p_{aft} \), the temperature \( T_{aft} \) and the molar fraction \( y_{aft} \) are measured. It follows:
The adsorbed molar quantity can be calculated as the difference of moles in the vapour before and after adsorption:

\[
    n_{\text{ads}} = n_{\text{bef}} - n_{\text{aft}} = \frac{y_{\text{bef}} P_{\text{bef}} V_{\text{mix}}}{Z_{\text{bef}} \mathcal{R} T_{\text{bef}}} - \frac{y_{\text{aft}} P_{\text{aft}} V_{\text{ads}}}{Z_{\text{aft}} \mathcal{R} T_{\text{ads}}}
\]  

(4.3)
The loading $n$ of the adsorbent is the ratio of the adsorbed moles to the mass of the adsorbent:

$$n = \frac{n_{\text{ads}}}{m_{\text{ads}}} \quad (4.4)$$

The equilibrium pressure $p_{\text{equilibrium}}$ for the adsorption isotherm is the partial pressure of the adsorptive in the carrier gas which is assumed not to be adsorbed. It is

$$p_{\text{equilibrium}} = y_{\text{aff}} \cdot p_{\text{aff}} \quad (4.5)$$

### 4.2. Packed bed method

In the packed bed method the calculation of the equilibrium is managed by examining the breakthrough curve of the adsorber. A mass balance is drawn around the packed bed. The adsorbed molar amount $N$ of an adsorptive related to the adsorbent mass in the packed bed $m_{\text{bed}}$ after a time $t$ can be calculated by

$$n = \frac{N_{\text{in}} - N_{\text{out}}}{m_{\text{bed}}} \quad (4.6)$$

With

$$N_{\text{in}} = \frac{\rho_{\text{in}} V_{\text{in}}}{M_{\text{in}}} \quad \text{and} \quad (4.7a)$$

$$N_{\text{out}} = \frac{\rho_{\text{out}} V_{\text{out}}}{M_{\text{out}}}$$

it follows

$$n = \frac{\rho_{\text{in}} V_{\text{in}} - \rho_{\text{out}} V_{\text{out}}}{M m_{\text{bed}}} \quad (4.8)$$
where $\rho$ is the partial density of the adsorptive in kg/m$^3$, $V$ the gas volume in m$^3$ and $M$ the molecular mass of the adsorptive in kg/mol. The law of ideal gases delivers the following relationship

$$\rho = \frac{\rho_{stand} T_{stand} p}{T_{ads} P_{stand}} \quad (4.9)$$

The index stand means standard state ($T_{stand} = 273.15$ K, $p_{stand} = 1.01325 \times 10^5$ Pa) and $\rho_{stand}$ is the standard density of the adsorptive.

The gas volumes which have passed through the packed bed from $t = 0$ to breakthrough can be determined via integration over the time. This calculation is demonstrated exemplarily for the outlet stream. The outlet volume stream $V_{out}(t)$ is composed of the carrier gas stream $V_C(t)$ and the adsorptive flow $V_{out,ads}(t)$ with the molar fraction $y_{out,ads}$, so

$$V_{out}(t) = V_C(t) + V_{out,ads}(t)$$

$$\dot{V}_{out}(t) = \dot{V}_C + \dot{V}_{out,ads}(t) \quad (4.10)$$

The adsorptive flow is then

$$\dot{V}_{out,ads}(t) = \dot{V}_C - \dot{V}_{out}(t) = \frac{\dot{V}_C}{1 - y_{out,ads}} - \dot{V}_C$$

$$\dot{V}_{out,ads}(t) = \dot{V}_C \frac{y_{out,ads}(t)}{1 - y_{out,ads}(t)} \quad (4.11)$$

An analogous equation for the inlet adsorptive flow can be written where the inlet molar fraction of the adsorptive $y_{in,ads}$ is constant:

$$\dot{V}_{in,ads}(t) = \dot{V}_C \frac{y_{in,ads}}{1 - y_{in,ads}} \quad (4.12)$$

From equation (4.10) it follows for the carrier gas stream
with \( w_G \) as the gas velocity in the inlet which is flow controlled and \( d \) as the inner diameter of the inlet pipe. By a combination of equations it follows for the equilibrium loading

\[
\dot{V}_c = w_G \frac{d^2 \pi}{4} (1 - y_{in, ads})
\]  

(4.13)

By continuous measuring of the mole fraction by a gas chromatograph the loading can be calculated from the partial pressure. Schweighart [36] could reach low pressure limits of 1.2 Pa with this method in adsorption systems like CO\(_2\)-MS5A, C\(_2\)H\(_4\)-MS5A, C\(_2\)H\(_6\)-MS5A and C\(_3\)H\(_8\)-MS5A.

### 4.3. Zero length column (ZLC) method

The zero length column technique was introduced in the beginning as a simple and rapid approach for the study of sorption kinetics. If the same kind of experiment is performed at a sufficiently low flow rate, the desorption rate will be determined by convection under equilibrium conditions rather than by the desorption kinetics. The effluent concentration history directly yields the equilibrium isotherm. The possibility of using this approach to measure Henry constants was suggested by Ruthven et al. [89,90].

In a ZLC experiment a couple of layers of zeolite is equilibrated in a short adsorber with an adsorptive of known partial pressure. At time \( t = 0 \) the feed (carrier gas with adsorptive) is switched to the pure carrier at constant flow rate. The concentration of the desorbed adsorbate in the outlet stream of the ZLC is continuously measured. The adsorber is so short that in can be treated as an ideal stirred tank reactor. The justification for this is as follows: The two border cases for the residence time behaviour of fluids in a pipe stream are the plug flow reactor without axial dispersion and the ideal stirred tank reactor with a very large axial mixing. Characteristic for this is the Bodenstein number \( Bo \) [93] with
\[ Bo = \frac{wL}{D_{ax}} \] (4.16)

where \( D_{ax} \) is the axial dispersion coefficient in the pipe, \( w \) the velocity of the fluid and \( L \) the length of the pipe. With \( L \rightarrow 0 \), as it occurs in a ZLC, the Bodenstein number goes towards zero. This corresponds to the case of the ideal stirred tank reactor. With this assumption it can be derived that the concentration of the outlet stream of the ZLC after \( t = 0 \) is equal to the inner concentration of the adsorber. The differential mass balance of the adsorptive is

\[
m_{\text{ads}} \frac{dn}{dt} + V_G \frac{dc}{dt} + \dot{V}_G c(t) = 0
\] (4.17)

where \( V_G \) is the gas volume in the adsorber, \( c \) the concentration of adsorptive in the gas phase in \( \text{mol/m}^3 \), \( \dot{V}_G \) the gas stream in and \( t \) the time. Generally, the outlet stream is not the same as the carrier gas stream and equation (4.10) is valid. The adsorptive stream is equal to the third summand in equation (4.17):

\[ \dot{N}_{\text{ads}} = \dot{V}_G c(t) \] (4.18)

With the mole fraction \( y_{\text{out,ads}}(t) \) and the overall number \( C \) of moles per \( \text{m}^3 \) it is

\[ c = C y_{\text{out,ads}}(t) \] (4.19)

Equation (4.10) can be rewritten in

\[ \dot{N}_{\text{ads}} = \dot{V}_C \frac{C y_{\text{out,ads}}(t)}{\left(1 - y_{\text{out,ads}}(t)\right)} \] (4.20)

The term \( dc/dt \) in equation (4.17) can be rewritten to
\[
\frac{dc}{dt} = \frac{d(Cy_{\text{out,ads}}(t))}{dt} = y_{\text{out,ads}}(t)\frac{dC}{dt} + C\frac{dy_{\text{out,ads}}(t)}{dt} = C\frac{dy_{\text{out,ads}}(t)}{dt}
\]  

(4.20)

because in an isothermal system the overall number of moles per volume, C, does not change which means that \( \frac{dC}{dt} = 0 \).

Equation (4.17) can be rewritten into the general form

\[
m_{\text{ads}}\frac{dn}{dt} + V_G C \frac{dy_{\text{out,ads}}(t)}{dt} + V_C C \frac{y_{\text{out,ads}}(t)}{(1 - y_{\text{out,ads}}(t))} = 0
\]

(4.21)

or

\[
dn = -V_C C \frac{y_{\text{out,ads}}(t)}{(1 - y_{\text{out,ads}}(t))} \frac{dt}{m_{\text{ads}}} - V_G C \frac{dy_{\text{out,ads}}(t)}{m_{\text{ads}}}
\]

(4.22)

At \( t = \infty \) it is \( y_{\text{out,ads}} = 0 \) and \( n = 0 \). Now the start loading \( n_{t=0} \) can be calculated:

\[
\int_{n_{t=0}}^{0} dn = -\int_{0}^{t_{\text{out}}} \frac{V_G C}{m_{\text{ads}}} \frac{y_{\text{out,ads}}(t)}{(1 - y_{\text{out,ads}}(t))} dt - \int_{0}^{t_{\text{out}} -} \frac{V_C C}{m_{\text{ads}}} \int_{y_{\text{out,ads}, t=0}}^{0} dy_{\text{out,ads}}(t)
\]

(4.23)

Therefore, it is

\[
n_{t=0} = -\int_{0}^{t_{\text{out}}} \frac{V_G C}{m_{\text{ads}}} \frac{y_{\text{out,ads}}(t)}{(1 - y_{\text{out,ads}}(t))} dt - \int_{0}^{t_{\text{out}} -} \frac{V_C C}{m_{\text{ads}}} (y_{\text{out,ads}}(t) - y_{\text{out,ads}, t=0})
\]

(4.24)

The loading \( n \) at time \( t \) can be calculated via equation (4.22) with

\[
n = n_{t=0} - \int_{0}^{t} \frac{V_G C}{m_{\text{ads}}} \frac{y_{\text{out,ads}}(t)}{(1 - y_{\text{out,ads}}(t))} dt - \int_{0}^{t} \frac{V_C C}{m_{\text{ads}}} (y_{\text{out,ads}}(t) - y_{\text{out,ads}, t=0})
\]

(4.25)

With equation (4.24) we get for the loading \( n \):
By integrating the adsorption isotherm in dependence of the measured concentration $c$ the loading $n$ is obtained. This can be converted into partial pressure by means of the law of ideal gases.

### 4.4. Concentration pulse chromatography method

The use of the concentration pulse chromatography for adsorbent screening is very attractive since it is relatively inexpensive to set-up [91,92]. Further, this method is capable of characterising adsorbents faster than other methods.

With the concentration pulse method, a pulse of sample is injected into the carrier gas stream and passes through an adsorbent packed column. The response of the column is measured as concentration vs. time at the exit of the column. From this response peak a mean retention time of the sample, $\tau$, is determined experimentally with

$$
\tau_D = \int_0^\infty c(t - \tau_D) dt \quad (4.27)
$$

The term $\tau_D$ is the mean dead time of the system. This dead time is the time required for a sample pulse to pass the empty volume of the interconnecting tubing from injection point to the detector and void space in the packed column.

With the that carrier gas composition the mean retention time is related to the effective isotherm slope, $K$, by

$$
\tau = \frac{L}{w} \left(1 + \frac{(1 - \varepsilon_{\text{bed}})}{\varepsilon_{\text{bed}}} K\right) \quad (4.28)
$$
where $\varepsilon_{\text{bed}}$ is the bed porosity. The dimensionless K factor can be transformed to the dimensional Henry coefficient in mol/(kg*Pa) by

$$He = \frac{K}{RT \rho_{\text{pellet}}}$$  \hspace{1cm} (4.29)

where $\rho_{\text{pellet}}$ is the apparent density of the adsorbent. With the former equations (4.27) and (4.28) inserted in equation (4.29) it follows

$$He = \left[ \frac{\int_0^w c(t - \tau_D) dt}{\int_0^w c dt} \cdot \frac{w}{L} - 1 \right] \cdot \frac{\varepsilon_{\text{bed}}}{1 - \varepsilon_{\text{bed}}} \cdot \frac{1}{RT_{\text{ads}} \rho_{\text{pellet}}}$$  \hspace{1cm} (4.30)

The concentration pulse method is also applicable for determining binary adsorption isotherms [91,92].
5. Prediction of Isotherms for $p \to 0$ (Henry)

The *Henry* coefficient is the first step in developing a pure component adsorption isotherm that allows for overall prediction of the adsorption equilibrium. It is characteristic for the region of diluted concentrations. In this work it is shown that the Henry coefficient is not only dependent on the adsorption temperature but also on the properties of the adsorptive and adsorbent themselves. It is a picture of the prevailing interaction forces between the gas and solid molecules and ions. Understanding the basic mechanisms of adsorption opens the door to an a priori approach of calculating adsorption isotherms in a wide concentration range.

An adsorption isotherm in the diluted concentrations region is described by the *Henry* law

$$n = He \ p$$  \hspace{1cm} (5.1)

where $n$ is the loading in mol/kg, $He$ the *Henry* coefficient in mol/(kg*Pa) and $p$ the equilibrium pressure in Pa. For graphical purposes this means that the loading $n$ is directly proportional to $p$ with the slope $He$. All adsorption isotherms intersect with the origin of the coordinate system. Logarithmising both sides of equation (5.1) leads to equation

$$\log(n) = \log(He) + \log(p)$$  \hspace{1cm} (5.2)

with slope 1 in a graph with double logarithmic axes. The intercept of the curve with the $\log(n)$-axes is equal to $\log(He)$ if the $\log(p)$-axes begins at 1 Pa. Figure 5.1 shows two different plots, one with linear and one with double logarithmic axes.
Besides dimensionally correctness another important principle in chemical engineering is the thermodynamic consistency of derivations. This goal is retained in this work when the Henry coefficient is deduced from chemical potential equilibria. As next step in this Chapter the Henry coefficient is calculated in the case of energetically homogeneous adsorbents. An analytical function is derived from theoretical considerations which is a powerful instrument for process engineers. The last step introduces the general case of energetically heterogeneous adsorbents.

Figure 5.1: Two different views of adsorption isotherms in the low-pressure region.
5.1. Thermodynamic consistency

In Chapter 3 several descriptions of adsorption equilibria were introduced of which some could be derived from thermodynamic consistent considerations. The *Langmuir* isotherm is the most famous one. This work follows that principle.

Besides disperse forces mainly electrostatic forces influence the adsorptive during exposure to an electrical field, e.g. the field of an ionic crystal lattice of a zeolite [8]. In general these electrostatic forces contribute in a non negligible degree to the adsorption equilibrium of an adsorptive with a solid surface. The overall adsorption potential $\Phi$ can therefore be written as

$$\Phi = \sum \Phi_{\text{gas-solid}} = \Phi_{\text{indind}} + \Phi_{\text{indcha}} + \Phi_{\text{dipind}} + \Phi_{\text{dipcha}} + \Phi_{\text{quadind}} + \Phi_{\text{quadcha}} + \sum \Phi_{\text{adsads}}$$ (5.3)

The partial potentials are the integrated interaction energies of the adsorbate molecule with the solid continuum structure or with other adsorbate molecules. They describe the following interactions:

- The interaction of the induced dipole of the gas molecule with the induced dipole of the solid molecule ($\Phi_{\text{indind}}$),
- the interaction of the induced dipole of the gas molecule with the electrical charge of the solid molecule ($\Phi_{\text{indcha}}$),
- the interaction of the permanent dipole of the gas molecule with the induced dipole of the solid molecule ($\Phi_{\text{dipind}}$),
- the interaction of the permanent dipole of the gas molecule with the electrical charge of the solid molecule ($\Phi_{\text{dipcha}}$),
- the interaction of the permanent quadrupole moment of the gas molecule with the induced dipole of the solid molecule ($\Phi_{\text{quadind}}$) and
- the interaction of the permanent quadrupole of the gas molecule with the electrical charge of the solid molecule ($\Phi_{\text{quadcha}}$).
In the following study for determining the Henry coefficient one important assumptions is that the interactions between the adsorbate molecules are negligible. The physical cause for this is the low concentration or partial pressure of the adsorbate molecules in the Henry region, so that they do not interact with each other but only with the solid surface. It is

$$\sum_j \Phi_{adsads} = 0 \quad (5.4)$$

A second assumption is that the solid elements do not have a permanent dipole or quadrupole moment.

When two phases coexist in a system equilibrium is reached between them after a certain time. In equilibrium state the chemical potentials $\mu$ of the two phases are equal. For the adsorptive and adsorbate phases it follows that

$$\mu_{adsorbive} = \mu_{adsorbate} \quad (5.5)$$

The chemical potential is a function of pressure $p$ and temperature $T$ with

$$\mu = f(T, p) \quad (5.6)$$

In the Henry region with its low pressure the adsorptive behaves like an ideal gas. Its chemical potential is defined as

$$\mu_{adsorbive}(T, p) = \mu_{adsorbive}(T_{ads}, p_{ref}) + kT_{ads} \ln \left( \frac{p_{ads}}{p_{ref}} \right) \quad (5.7)$$

where $p_{ref}$ is the reference pressure in Pa, $\mu_{adsorbive}(T_{ads}, p_{ref})$ the reference chemical potential of the adsorptive and $k$ the Boltzman's constant. The second term is the correction from pressure $p_{ref}$ to the adsorption equilibrium pressure of the gas $p_{ads}$. The chemical potential of the adsorbate can be expressed as
\[ \mu_{\text{adsorbate}}(T, p) = \mu_{\text{adsorbate}}(T_{\text{ads}}, p_{\text{ref}}) + kT_{\text{ads}} \ln \left( \frac{p_{\text{ads}} + dp_{\text{adsorbate}}}{p_{\text{ref}}} \right) + \sum \Phi_{\text{gas-solid}} \quad (5.8) \]

where \( \mu_{\text{adsorbate}}(T_{\text{ads}}, p_{\text{ref}}) \) is the reference chemical potential of the adsorbate and \( dp_{\text{adsorbate}} \) is the difference pressure which acts additionally to the adsorbate layer. The second term is therefore also a correction from the reference pressure to the overall pressure of the adsorbate. The third term takes into account the sum of interactions between the adsorbate and the solid. With the assumption

\[ \mu_{\text{adsorbate}}(T_{\text{ads}}, p_{\text{ref}}) = \mu_{\text{adsorbate}}(T_{\text{ads}}, p_{\text{ref}}) \quad (5.9) \]

and that the adsorbate behaves like an ideal gas and according to

\[ dp_{\text{adsorbate}} = \frac{\mathcal{R} T_{\text{ads}} dn}{dv_{\text{solid}}} \quad (5.10) \]

it follows with equations (5.7) and (5.8) that

\[ kT_{\text{ads}} \ln \left( \frac{p_{\text{ads}}}{p_{\text{ref}}} \right) = kT_{\text{ads}} \ln \left( \frac{p_{\text{ads}} + \mathcal{R} T_{\text{ads}} dn}{p_{\text{ref}}} \right) + \sum \Phi_{\text{gas-solid}} \quad (5.11) \]

where \( dv_{\text{solid}} \) is the specific volume element of the solid. With algebraic conversions and equation (5.1) it follows that

\[ He = \frac{n}{p} = \frac{1}{\mathcal{R} T_{\text{ads}}} \int_{v_{\text{solid}}=0}^{v_{\text{solid}}} \left[ \exp \left( -\frac{\sum \Phi_{\text{gas-solid}}}{kT_{\text{ads}}} \right) - 1 \right] dv_{\text{solid}} \quad (5.12) \]

The specific volume element of the solid can be expressed with its specific surface and the perpendicular distance \( z \) of the gas molecules from the surface:

\[ dv_{\text{solid}} = S_{\text{BET}} \, dz \quad (5.13) \]
With equation (5.12) it follows the well known equation for the *Henry* coefficient expanded with the overall interaction terms:

\[
He = \frac{S_{\text{BET}}}{kT_{\text{ads}}} \int_0^{z_{\text{max}}} \left[ \exp \left( \frac{-\Phi_{\text{gas-solid}}}{kT_{\text{ads}}} \right) - 1 \right] dz
\]  

(5.14)

The integration constant \( z_{\text{max}} \) depends on the structure of the solid. For massive solids \( z_{\text{max}} \) is infinity, for porous solids it depends on the pore volume [47]. With equations (5.3) and (5.4) the thermodynamic consistent equation for the *Henry* coefficient becomes

\[
He = \frac{S_{\text{BET}}}{kT_{\text{ads}}} \int_0^{z_{\text{max}}} \left[ \exp \left( \frac{-\Phi_{\text{ind}}}{kT_{\text{ads}}} \right) - 1 \right] dz
\]  

(5.15)

### 5.2. Energetic homogeneous adsorbents

A special case of equation (5.15) is the adsorption of arbitrary gases on energetic homogeneous adsorbents like active carbon or silicalite-1. For this case Maurer [26] derived the potential function for the interaction energy \( \Phi_{\text{ind}}(z) \) which depends on the critical properties of the adsorptive and the solid properties of the adsorbent. The *Henry* coefficient reduces in this case to:

\[
He = \frac{S_{\text{BET}}}{kT_{\text{ads}}} \int_0^{z_{\text{max}}} \left[ \exp \left( \frac{-\Phi_{\text{ind}}(z)}{kT_{\text{ads}}} \right) - 1 \right] dz
\]  

(5.16)

It is referred to the literature for the derivation of the interaction energy \( \Phi_{\text{ind}}(z) \) [26]. For consistency the main formulas shall be mentioned in this work with

\[
\Phi_{\text{ind}}(z) = -\frac{4\pi C_{i,j} \rho_j}{3(\sigma_{i,j} + z)}
\]  

(5.17)
where $C_{ij}$ is an interaction constant between the adsorbate molecule and the solid atoms, $\sigma_{ij}$ the minimum contact distance between the adsorption participants and $\rho_j$ the density of the solid. Figure 5.2 shows a principle scheme for the distance of the adsorbate from the solid.

![Figure 5.2: Principle scheme for the distance of the adsorbate from the solid [26].](image)

The distance between the adsorbate sphere centre and the centre of the closest solid atom in its vicinity is $(\sigma_{ij} + z)$. The minimum distance $\sigma_{ij}$ is calculated by the arithmetic mean of the van-der-Waals diameters of the adsorbate and the solid molecules with

$$
\sigma_{i,j} = \frac{1}{2}(\sigma_{i,i} + \sigma_{j,j}) \tag{5.18}
$$

*Maurer* [26] derived the van-der-Waals diameter of the adsorptive from its critical properties. It is

$$
\sigma_{i,i} = \sqrt[3]{\frac{3kT_c}{16\pi p_c}} \tag{5.19}
$$

where $T_c$ and $p_c$ are the critical temperature and critical pressure, respectively. The van-der-Waals diameter of the solid can be found in the literature. If not it is referred to Section 5.2.2 for the derivation of the parameter $\sigma_{i,i}$. 
The interaction constant itself can be formulated as

\[ C_{i,j} = \frac{9 \Re \sigma_{i,j}^3}{16 \rho_j N_A} \sqrt[3]{\frac{2 Ha_j}{\pi^3 \sigma_{j,i}^3}} \frac{T_c}{p_c} \]  \hspace{1cm} (5.20)

where \( Ha_j \) is the Hamaker constant of the solid.

### 5.2.1. The dimensionless Henry curve

The interaction energy \( \Phi_{\text{ind}} \) of two induced dipoles is also called the London dispersion energy [5]. This dispersion energy can also be understood by the following argument. Although the time-averaged dipole moment is zero for molecules without a dipole, there exists at any time a finite value. An electromagnetic field emanates from this dipole moment and induces a dipole in a nearby molecule. These dispersion forces are omnipresent, they are always attractive.

The scope of this Section is to formulate a dimensionless function for the Henry curve considering only London dispersion forces (Hamaker dominant). It is based on the advancement of the Henry function formulated by equation (5.16) in the case of energetic homogenous adsorbents. With equations (5.17) and (5.20) the interaction energy \( \Phi_{\text{ind}}(z) \) can be rewritten by dividing by the energy unit \((kT_{\text{ads}})\)

\[ \frac{\Phi_{\text{ind}}(z)}{kT_{\text{ads}}} = -\frac{4 \pi \rho_j}{3(\sigma_{i,j} + z)^3} \frac{9 \Re \sigma_{i,j}^3}{16 \rho_j N_A} \sqrt{\frac{2 Ha_j}{\pi^3 \sigma_{j,i}^3}} \frac{T_c}{p_c} \]  \hspace{1cm} (5.21)

With

\[ \Re = k N_A \]  \hspace{1cm} (5.22)

and the binomial formula

\[ (a + b)^3 = a^3 + 3a^2b + 3ab^2 + b^3 \]  \hspace{1cm} (5.23)
equation (5.21) can be simplified:

\[
\phi_{\text{indad}}(z) = -\frac{3\sigma_{i,j}^3}{4(\sigma_{i,j}^3 + 3\sigma_{i,j}^2 z + 3\sigma_{i,j} z^2 + z^3)} \sqrt{\frac{2Ha_j}{\pi \sigma_{j,k}^3 p_c T_{\text{ads}}}} T_c
\]  

(5.24)

Therefore the Henry coefficient can then be expressed as

\[
He = \frac{S_{\text{BET}}}{\mathcal{R} T_{\text{ads}}} \int_0^{z_{\text{max}}} \left[ \exp \left( \frac{3\sigma_{i,j}^3}{4(\sigma_{i,j}^3 + 3\sigma_{i,j}^2 z + 3\sigma_{i,j} z^2 + z^3)} \sqrt{\frac{2Ha_j}{\pi \sigma_{j,k}^3 p_c T_{\text{ads}}}} \right) - 1 \right] dz
\]  

(5.25)

By dividing both sides by the minimum contact distance of the adsorbate molecule and the solid atom \(\sigma_{i,j}\) equation (5.25) can be rearranged to

\[
\frac{He \mathcal{R} T_{\text{ads}}}{S_{\text{BET}} \sigma_{i,j}} = \int_0^{z_{\text{max}}} \left[ \exp \left( \frac{3}{4(1 + 3 \frac{z}{\sigma_{i,j}} + 3 \left( \frac{z}{\sigma_{i,j}} \right)^2 + \left( \frac{z}{\sigma_{i,j}} \right)^3)} \sqrt{\frac{2Ha_j}{\pi \sigma_{j,k}^3 p_c T_{\text{ads}}}} \right) - 1 \right] d\left( \frac{z}{\sigma_{i,j}} \right)
\]  

(5.26)

Both sides of equation (5.25) are now dimensionless. The left side is defined by Mersmann et.al. [27] as the dimensionless Initial or Henry Loading \(IL\) with

\[
IL \equiv \frac{He \mathcal{R} T_{\text{ads}}}{S_{\text{BET}} \sigma_{i,j}}
\]  

(5.27)

which is mainly a function of the Interaction Parameter \(IP\) with

\[
IP \equiv \frac{T_c}{T_{\text{ads}}} \sqrt{\frac{2Ha_j}{\pi \sigma_{j,k}^3 p_c}}
\]  

(5.28)

and the integration variable
\[ x_{\text{max}} \equiv \frac{z_{\text{max}}}{\sigma_{i,j}} \]  

(5.29)

With the reduced distance

\[ x \equiv \frac{z}{\sigma_{i,j}} \]  

(5.30)

and the definitions

\[ y \equiv IL \]  

(5.31)

and

\[ a = \frac{4}{3 \, IP} \]  

(5.32)

the dimensionless Henry function can be expressed as

\[ y(a, x) = IL = \int_0^{x_{\text{max}}} \left[ \exp\left(\frac{3}{4(1 + 3ax + 3ax^2 + x^3)} \, IP \right) - 1 \right] dx = \int_0^{x_{\text{max}}} \left[ \exp\left(\frac{1}{a + 3ax + 3ax^2 + ax^3} \right) - 1 \right] dx \]  

(5.33)

This integral cannot be solved analytically. It was numerically analysed with commercially available mathematical programs. Nevertheless for given values of \( a \) and \( x_{\text{max}} \) the integral can be calculated on a numerical basis for example with MathCAD. In this context it is important to mention that the integration parameter \( a \) is not a function of \( x \). The constant \( a \) only depends on the solid and adsorptive properties (the Hamaker constant \( H_{ij} \) and the van-der-Waals diameter \( \sigma_j \) of the solid, the critical temperature \( T_c \) and the critical pressure \( p_c \) of the adsorptive) and also on the adsorption conditions (the adsorption temperature \( T_{\text{ads}} \)).
As next step the interval [0.1;30] of the dimensionless interaction parameter IP was examined. This interval can be recalculated via equation (5.32) to an interval [13.33;0.0444] of the integration parameter a. Through physical examinations a minimum and maximum value for the reduced distance $x_{\text{max}}$ was derived. For this the following assumptions were made:

- The helium atom He has the smallest van-der-Waals diameter of gases which is $\sigma_{\text{He}} = 2.66 \times 10^{-10}$ m.
- The maximum pore diameter d of microporous solids is 2 nm = $20 \times 10^{-10}$ m and limits the distance of an adsorptive molecule from the solid surface.
- The van-der-Waals diameter of a solid atom is approximately $4.0 \times 10^{-10}$ m.
- Large adsorptive molecules have a maximum van-der-Waals-diameter of $5.5 \times 10^{-10}$ m.
- $x_{\text{max}}$ is calculated via equation (5.34) to

$$x_{\text{max}} = \frac{z_{\text{max}}}{\sigma_{i,j}} = \frac{d - \sigma_{i,j}}{\frac{1}{2}(\sigma_{i,j} + \sigma_{j,i})} \quad (5.34)$$

The values for $x_{\text{max}}$ are then calculated as a minimum value of approximately 0.9 and a maximum value of 2. With these values and by numerical calculations of the integral (5.33) the table 5.1 was generated. Practically the integration values for the dimensionless Henry loading IL do no longer differ above a value of 2 for the interaction parameter IP. Both limits for the dimensionless Henry curve are shown in figure 5.3. It can be seen that the Henry curve only depends on the interaction parameter IP. It has to be mentioned that the curve does not cross the value pair (0/1) which is shown by Mersmann et al. [27] as the thermodynamic consistent point to be crossed.

For engineering purposes it would be easier to have an analytical function for determining the Henry coefficient in the case of energetic homogenous adsorbents. Therefore, in the next step an analytical function is introduced which is a powerful and easy instrument for calculating the Henry coefficient.

Figure 5.3: The dimensionless Henry curve – numerical values (equation (5.33)).
The numerical values of figure 5.3 are approximated by the function

\[ IL = \exp\left(p_1 IP^{p_2}\right) \]  

(5.35)

where \( p_1 \) and \( p_2 \) are parameters adjusted to the real numerical values of the integral (5.33). The adjustment was performed by the numerical software Maple. For the two cases of \( x_{\text{max}} = 0.9 \) and \( x_{\text{max}} = 2 \) the parameter values \( p_1 = 0.3312917 \) and \( p_2 = 1.1803227 \) for \( x_{\text{max}} = 0.9 \) and \( p_1 = 0.3312936 \) and \( p_2 = 1.1803211 \) for \( x_{\text{max}} = 2.0 \) were obtained. The two parameter sets do not differ significantly. For this work the second set was chosen. The exponential function (5.35) with the second set is shown and compared with the numerical values in figure 5.4.

Figure 5.4: The dimensionless Henry curve – analytical regression.
The regression curve goes through the thermodynamic consistent point (0/1) [27]. The quality of the analytical form of the Henry curve is discussed in Chapter 7. It is shown there also that this function does not cover only the adsorption behaviour of energetic homogenous adsorbents like active carbon and silicalite-1 but also the case of non-polar adsorbents paired with energetic heterogeneous adsorbents like zeolites. This is a very new aspect derived for the first time in this work.

One of the assumptions in this Section was the value of the van-der-Waals diameter of solids. The diameter for active carbon coal was chosen to be that of the carbon atom [26], so $\sigma_{\text{active carbon}} = 3.40 \times 10^{-10}$ m. In most cases there are no literature data for this parameter. So in the next Section a way for determining this solid property is derived.

5.2.2. The van-der-Waals diameter of solids

Because of the very strong dependency of the Henry curve on the interaction parameter $IP$ the van-der-Waals diameter of the solid has also a great significance. It goes down as the third power in the calculation of the interaction parameter. With the assumption that the Henry curve is thermodynamic consistent and characterised accurately by equation (5.35) the following approach for the derivation of the diameter $\sigma_j$ of the solid can be made:

$$f(\sigma_j) = \frac{2He^{3RT_{ads}}}{(\sigma_i + \sigma_j)S_{BET}} = g(\sigma_j) = \exp\left( p_1 \left( \frac{T_c}{T_{ads}} \frac{2Ha_j}{\pi \sigma_j^3 p_c} \right)^{p_2} \right)$$

It is:

$$f(\sigma_j) - g(\sigma_j) = 0$$

where $f$ and $g$ are functions of the diameter $\sigma_j$ as defined in equation (5.36). There is only one unknown variable in equation (5.37), the diameter $\sigma_j$, if at least one adsorption isotherm of the solid is known. For energetic homogenous adsorbents the choice of the adsorptive is not critical. For energetic heterogeneous adsorbents the
adsorptive should have no dipole or quadrupole moment. Most of the solid’s surface is examined by the BET-isotherm of nitrogen at 77 K as adsorption temperature. So there is at least one experiment set of parameters (Henry coefficient, adsorption temperature, critical properties and van-der-Waals diameter of the adsorptive, specific surface and Hamaker constant of the solid) for each solid available without further experimental work. In this study propane adsorption isotherms were taken to calculate the van-der-Waals diameter of the examined solids. In the case of NaY methane was taken. The zero point search as derived in equations (5.36) and (5.37) was conducted with the program MathCAD. Table 5.2 shows the results.

</table>
The results show that the van-der-Waals diameters of zeolites are in the same magnitude as that of active carbon. Furthermore the chosen diameter for active carbon of $\sigma_{\text{active carbon}} = 3.40 \times 10^{-10}$ m is approved by this calculation by an accuracy of $\pm 2.9\%$.

### 5.3. Energetic heterogeneous adsorbents

In order to calculate the Henry coefficient for the adsorption of polar gases on energetic heterogeneous adsorbents like zeolites it is necessary to take into account all the possible interaction potentials between the adsorbate and the solid atoms. In this Section analytical functions for these potentials are derived. Consequently the Henry function of equation (5.15) can then be extended to an integral which is finally numerically solvable. Later it will be shown that the interaction energy $\frac{\Phi_{\text{indind}}}{kT_{\text{ads}}}$ is only approximately 50 % of the sum of all interaction energies in the case of polar gases.

#### 5.3.1. The range of polarities

In the following potential calculations the polarity properties of the adsorptives are important factors. Their possible value intervals can be

- between $2.2 \times 10^{-41}$ (C$^2$m$^2$/J) (helium) and $2.13 \times 10^{-39}$ (C$^2$m$^2$/J) (n-decane) for the polarisability $\alpha_i$ of the gas molecule.
- The dipole moment $\mu_i$ can be between 0 (methane) and $1.0 \times 10^{-29}$ C*m (acetone).
- The quadrupole moment $Q_i$ can be between 0 (methane) and $6.21 \times 10^{-39}$ C*m$^2$ (anthracene).

#### 5.3.2. Induced dipole gas – electrical charge solid interaction (indcha)

The assumption for the derivation of the interaction between an induced dipole of a gas molecule and an electrical charge of a solid atom is that the solid is composed of so-
called average atoms with equal properties. In reality this is not true but it is effective for the characterisation of the interaction energy.

The proposed route of van der Hoeven [41] for the calculation of the Hamaker constant is based upon a subdivision of the solid molecules into atoms, which all have an average composition and polarisability identical to that of the solid molecule. The constants (London constant, polarisability, number density) are then calculated from these average atomic properties. In this approach it is further supposed that the atoms are all bonded by semi-polar bonds and that only the bond-forming valence electrons contribute to the disperse energetic waves with respect to the Hamaker constant.

According to Münstermann [131] the adsorption of polar or polarisable molecules is preferred by molecular sieves. These adsorbents are attracted by the positive charged cations of the zeolite cages. This effect has to be taken into account when dealing with charge interactions for calculating the Henry coefficient of arbitrary gases.

The potential energy $E_{\text{indcha}}$ between two molecules or atoms, of which one is polarisable and the other one possesses an electrical charge, can be described by Hirschfelder [19]

$$E_{\text{indcha}}(r) = -\frac{1}{2r^4}\frac{\alpha_i q_j^2}{(4\pi\varepsilon_0 \varepsilon_r)^2}$$

(5.38a)

where $\alpha_i$ is the polarisability of the gas molecule in $(C^2*m^2)/J$, $q_j$ the effective charge of the average atom of the solid in C, $\varepsilon_0$ the permittivity of free space = $8.854*10^{-12}$ C/(V*m), $\varepsilon_r$ the relative permittivity of the adsorbent and $r$ the distance between the centre of the molecules in m. For calculation of the relative permittivity of microporous adsorbents the porosity of the solid has to be taken into account. It is assumed that

$$\varepsilon_r = \varphi \cdot 1 + (1 - \varphi) \cdot n^2$$

(5.38b)

where $\varphi$ is the porosity and $n$ the refractive index of the solid. For MS5A the relative permittivity is 1.73 with $\varphi = 0.5$ [24] and $n = 1.57$. 
From a summation of all pair potentials it follows the interaction potential of the gas molecule with the whole solid continuum. In general it is [21]

$$\Phi = \int_\sigma^\infty E(r) \rho_{j,at} \, 4 \pi r^2 \, dr$$

(5.39)

where \(\rho_{j,at}\) is the number density of solid atoms in \(1/m^3\) calculated with equation (3.92).

In this work the following general description of the interaction potentials was chosen:

$$\Phi = \int_{\sigma_i,j + z}^\infty E(r) \rho_{j,at} \, 4 \pi r^2 \, dr$$

(5.40)

The lower integration limit of equation (5.39) was substituted by \((\sigma_{i,j} + z)\) because the minimum distance between the molecules is \(\sigma_{i,j}\), also known as the minimum van-der-Waals contact distance. The effective mean charge of the average solid atom \(q_{j,at}\) depends on the average number of positive charged cations \(s_{\text{cations}}\) per solid atom. This property is introduced here for the first time as

$$s_{\text{cations}} = \frac{n_c}{n_a}$$

(5.41a)

where \(n_c\) are the number of positive charges and \(n_a\) the number of atoms in the solid molecule. For example for MS5A \(n_c = 12, n_a = 79\) and \(s_{\text{cations}} = 0.152\).

It follows for the effective mean charge that

$$q_j = s_{\text{cations}} \, e$$

(5.41b)

where \(e\) is the charge of one electron \((e = 1.60 \times 10^{-19} \text{ C})\). The interaction energy \(\Phi_{\text{indcha}}(z)\) is then due to equations (5.41b) and (5.38a)

$$\Phi_{\text{indcha}}(z) = \int_{\sigma_{i,j} + z}^\infty -\frac{1}{2} \frac{\alpha_r q_j^2}{r^4 \left(4 \pi \epsilon_0 \epsilon_r\right)^2} \rho_{j,at} \, 4 \pi r^2 \, dr = -\frac{1}{2} \frac{\alpha_r s_{\text{cations}}^2 e^2 \rho_{j,at}}{4 \pi \epsilon_0^2 \epsilon_r^2} \frac{1}{(z + \sigma_{i,j})}$$

(5.42a)
With the same substitution as in equation (5.30) and after dividing both sides of equation (5.42a) by the energy unit \((k^*T_{ads})\) one gets the reduced interaction energy

\[
\Phi_{ind}^{cha}(x) = -\frac{1}{kT_{ads}} \frac{\alpha_i s_{cations}^2 e^2 \rho_{j,at}}{\pi \varepsilon_0^2 \varepsilon_r^2 (kT_{ads})} \frac{1}{\sigma_{i,j}(x+1)}
\]

(5.42b)

The dimensionless interaction parameter for the actual case is then defined as

\[
A_{ind}^{cha} = \frac{\alpha_i s_{cations}^2 e^2 \rho_{j,at}}{8 \pi \varepsilon_0^2 \varepsilon_r^2 (kT_{ads}) \sigma_{i,j}}
\]

(5.43)

5.3.3. Permanent dipole gas – induced dipole solid interaction (dipind)

Gas molecules can have a permanent dipole when the atoms of different charge of the molecule compound are not arranged symmetrically to each other. For example, trifluormethane \(\text{CHF}_3\) has a dipole moment of 1.6 debye or \(5.344 \times 10^{-30}\) C\(\times\)m. Permanent dipoles induce a dipole in the attraction partner if this partner is polarisable. The potential attraction energy between two molecules is according to Debye [4]

\[
E_{dipind}(r) = -\frac{\mu_i \alpha_j}{r^6 \left(4 \pi \varepsilon_0 \varepsilon_r\right)^{\frac{3}{2}}}
\]

(5.44)

where \(\mu_i\) is the dipole moment of the gas molecule in Cm and \(\alpha_j\) the polarisability of a solid atom according to equation (4.49) in \((\text{C}^2\text{m}^2)/\text{J}\). In the following it is assumed that the solid atoms are induced from the polar gas molecules but do not have a permanent dipole themselves. The interaction energy of one polar gas molecule with the whole solid continuum is with equation (5.40)

\[
\Phi_{dipind}(z) = \int_{\sigma_{i,j}+z} E_{dipind}(r) \rho_{j,at} 4 \pi r^2 dr
\]

(5.45)

Therefore it is
\[ \Phi_{\text{dipind}} (z) = -\frac{\mu_j^2 \alpha_j \rho_{j,at}}{12 \cdot \pi \varepsilon_0^2 \varepsilon_r^2} \frac{1}{(\sigma_{i,j} + z)^3} \] (5.46)

After introduction of the reduced location variable \( x \) the reduced interaction energy permanent dipole gas – induced dipole solid is

\[ \frac{\Phi_{\text{dipind}} (x)}{kT_{\text{ads}}} = -\frac{\mu_j^2 \alpha_j \rho_{j,at}}{12 \cdot \pi \varepsilon_0^2 \varepsilon_r^2} \frac{1}{kT_{\text{ads}}} \frac{1}{\sigma_{i,j}^3} \frac{1}{(1 + x)^3} \] (5.47)

The dimensionless interaction parameter \( A_{\text{dipind}} \) is therefore

\[ A_{\text{dipind}} = \frac{\mu_j^2 \alpha_j \rho_{j,at}}{12 \cdot \pi \varepsilon_0^2 \varepsilon_r^2 kT_{\text{ads}}} \frac{1}{\sigma_{i,j}^3} \] (5.48)

5.3.4. Permanent dipole gas – electrical charge solid interaction (dipcha)

This interaction type is dominant for highly polar adsorptives like trifluromethane (CHF\textsubscript{3}), ammonia (NH\textsubscript{3}) and methanol (CH\textsubscript{3}OH). The potential attractive energy of a permanent dipole with a charged atom is quantified [19] with

\[ E_{\text{dipcha}} (r) = -\frac{1}{3 kT_{\text{ads}}} \frac{\mu_j^2 q_j^2}{r^4 \left(4 \pi \varepsilon_0 \varepsilon_r \right)^2} \] (5.49)

with already known parameters. The summation of the potential energy over the whole solid yields

\[ \Phi_{\text{dipcha}} (z) = \int_{z+\sigma_j} z E_{\text{dipcha}} (r) \rho_{j,at} 4\pi r^2 dr \] (5.50)

After integration and deviding by the energy unit (kT\textsubscript{ads}) and introducing the dimensionless variable \( x \) it follows for this interaction energy
\[
\Phi_{\text{dipcha}}(x) = \frac{\mu_i^2 s_{\text{cations}}^2 e^2 \rho_{f,\text{at}}}{12 \cdot \pi \varepsilon_0^2 \varepsilon_r^2 (kT_{\text{ads}})^2} \frac{1}{\sigma_{i,j} (1 + x)}
\]  
(5.51)

Then the dimensionless interaction parameter \( A_{\text{dipcha}} \) can be defined as

\[
A_{\text{dipcha}} = \frac{\mu_i^2 s_{\text{cations}}^2 e^2 \rho_{f,\text{at}}}{12 \cdot \pi \varepsilon_0^2 \varepsilon_r^2 (kT_{\text{ads}})^2} \]  
(5.52)

5.3.5. Quadrupole moment gas - induced dipole solid interaction (quadind)

The quadrupole moment is a fundamental property for the description of the molecular charge distribution [103]. In the theory of electricity there are two signs of electric charge. The net total charge is the monopole moment. If there are charges of two signs separated, then there exists a dipole moment along the line connecting the charges. If there are charges of both signs, but separated in a more complicated way, an electric quadrupole may be present. The quadrupole moment gives an indication of the derivation of the charge distribution of the adsorptive from spherical symmetry.

For gases with strong quadrupole moments like CO\(_2\) the previous potential phenomena are not sufficient to describe their great adsorption effect in the Henry region particularly because their permanent dipole is small or even zero in the case of benzene. The cause is that the quadrupole moment can also induce a dipole moment on the solid atoms or can interact with electrical charges of the adsorbent. For two molecules of which one has a quadrupole moment and the other is polarisable the potential energy is [19]

\[
E_{\text{quadind}}(r) = \frac{3 Q_i^2 \alpha_j}{2 (4 \pi \varepsilon_0 \varepsilon_r)^{1/2}} r^3
\]  
(5.53)

where \( Q_i \) is the quadrupole moment of the adsorptive in C*m\(^2\). It follows for the reduced interaction potential with the usual procedure as in the previous chapters that

\[
\Phi_{\text{quadind}}(x) = -\frac{3 Q_i^2 \alpha_j \rho_{f,\text{at}}}{40 \pi \varepsilon_0^2 e^2 \varepsilon_r} \frac{kT_{\text{ads}}}{\sigma_{i,j} (1 + x)^5}
\]  
(5.54)
Now the dimensionless interaction parameter $A_{\text{quadind}}$ can be directly specified as

$$A_{\text{quadind}} = \frac{3}{40} \frac{Q_j^2 \alpha_i \rho_{\text{at}}}{\varepsilon_i^2 \varepsilon_r^2 (k T_{\text{ads}}) \sigma_{i,j}^5}$$

(5.55)

5.3.6. Quadrupole moment gas – electrical charge solid interaction (quadcha)

This potential is in the same order of magnitude as the permanent dipole – electrical charge interaction. The potential energy between two molecules with a quadrupole moment and an electrical charge is according to Israelachvili [21]

$$E_{\text{quadcha}}(r) = -\frac{1}{20 k T_{\text{ads}}} \frac{Q_i^2 q_j^2}{(4 \pi \varepsilon_0 \varepsilon_r)^2 r^6}$$

(5.56)

It follows for the reduced interaction potential:

$$\Phi_{\text{quadcha}}(x) = -\frac{1}{240 k T_{\text{ads}}} \frac{Q_i^2 q_j^2 \rho_{\text{at}}}{(4 \pi \varepsilon_0 \varepsilon_r)^2 (k T_{\text{ads}})^2} \frac{1}{\sigma_{i,j}^3} \frac{1}{(1 + x)^3}$$

(5.57)

with the well known parameters of the adsorptive and the adsorbent. The dimensionless interaction parameter $A_{\text{quadcha}}$ is then

$$A_{\text{quadcha}} = \frac{Q_i^2 s_{\text{cation}}^2 \rho_{\text{at}}}{240 \pi \varepsilon_0^2 \varepsilon_r^2 (k T_{\text{ads}})^2 \sigma_{i,j}^5}$$

(5.58)

Later in chapter 7.2 the validity of this theoretical model according to the equations (5.24), (5.42b), (5.47), (5.51), (5.54) and (5.57) will be discussed.

5.3.7. Overall adsorption potential

The overall adsorption potential between a gas molecule and the solid continuum can be expressed as the sum of the partial potentials as shown in equation (5.3). Because
the Henry coefficient depends on the reduced overall potential \( -\sum \frac{\Phi_{\text{Gas-Solid}}}{kT_{\text{ads}}} \) as shown in equation (5.14) also the partial potentials will be expressed by reduced equations relative to the energetic unit \( kT_{\text{ads}} \). Therefore, the induced dipole – induced dipole interaction can be rewritten as:

\[
\frac{\Phi_{\text{indind}}(z)}{kT_{\text{ads}}} = -\frac{3\sigma_{i,j}^3}{4(\sigma_{i,j} + z)^3} \sqrt{\frac{2Ha_j}{\pi \sigma_{j,j}^3 p_c T_{\text{ads}}}}
\]

(5.59)

It is assumed that this potential is the London potential expressed by a function of the Hamaker constant of the solid and the critical parameters of the adsorptive. This item will be discussed in Chapter 7. With the additional equations (5.41b), (5.46), (5.50), (5.54) and (5.57) for the other partial potentials the reduced overall potential can be formulated in detail as shown in equation (5.60).

\[
-\frac{\Phi(z)}{kT_{\text{ads}}} = -\sum \frac{\Phi_{\text{gas-solid}}(z)}{kT_{\text{ads}}}
= -\frac{\Phi_{\text{indind}}(z) - \Phi_{\text{indcha}}(z) - \Phi_{\text{dipind}}(z) - \Phi_{\text{dipcha}}(z) - \Phi_{\text{quadind}}(z) - \Phi_{\text{quadcha}}(z)}{kT_{\text{ads}}}
\]

\[
= \frac{3\sigma_{i,j}^3}{4(\sigma_{i,j} + z)^3} \sqrt{\frac{2Ha_j}{\pi \sigma_{j,j}^3 p_c T_{\text{ads}}}} + \frac{\alpha_i s^2 cations e^2 \rho_{j,at}}{8kT_{\text{ads}} \pi \epsilon^2 \epsilon_r} \frac{1}{(\sigma_{i,j} + z)} +
\]

\[
+ \frac{\mu_j^2 \sigma_{j,at}}{12 \pi \epsilon_0^2 \epsilon_r kT_{\text{ads}}} \frac{1}{(\sigma_{i,j} + z)^3} + \frac{\mu_j^2 s^2 cations e^2 \rho_{j,at}}{12 \pi \epsilon_0^2 \epsilon_r (kT_{\text{ads}})^2} \frac{1}{(\sigma_{i,j} + z)} +
\]

\[
+ \frac{Q_j^2 \sigma_{j,at}}{40 \pi \epsilon_0^2 \epsilon_r kT_{\text{ads}}} \frac{1}{(\sigma_{i,j} + z)^3} + \frac{Q_j^2 s^2 cations e^2 \rho_{j,at}}{240 \pi \epsilon_0^2 \epsilon_r (kT_{\text{ads}})^2} \frac{1}{(\sigma_{i,j} + z)}
\]

(5.60)

In figure 5.5 the interactions of the adsorptive molecule with the solid continuum are presented graphically. The arrows are numbered respectively to the partial potential energies which occur between adsorptive and adsorbent. It has to be mentioned that the polarisability \( \alpha_i \) is the electronic polarisability of the molecule according to
Israelachvili [21] for further theoretic considerations. (Most important in figure 5.5 are the potentials indind, dipcha and quadcha, compare Section 7.3.5).

\[ -\Phi_{\text{dipcha}}(z) = \frac{\mu_i^2 s_{\text{cations}} e^2 \rho_{j,at}}{12\pi^2 e^2_{i} (kT_{ads})^2} \frac{1}{\left( \sigma_{i,j} + z \right)^3} \] \hspace{1cm} (5.51)

\[ -\Phi_{\text{quadind}}(z) = \frac{3Q_i^2 \alpha \rho_{j,at}}{40\pi e^2_{i} (kT_{ads})^2} \frac{1}{\left( \sigma_{i,j} + z \right)^3} \] \hspace{1cm} (5.54)

\[ -\Phi_{\text{quadcha}}(z) = \frac{Q_i^2 s_{\text{cations}} e^2 \rho_{j,at}}{240\pi^2 e^2_{i} (kT_{ads})^2} \frac{1}{\left( \sigma_{i,j} + z \right)^3} \] \hspace{1cm} (5.57)
5.3.8. *Henry* coefficient for energetic heterogeneous adsorbents

By inserting the interaction parameters into equation (5.15) the dimensionless *Henry* coefficient becomes

\[
IL = \int_0^{x_{\text{max}}} \left( \exp \left( \frac{A_{\text{dipcha}} + A_{\text{indcha}}}{(1 + x)} + \frac{A_{\text{indind}} + A_{\text{dipind}} + A_{\text{quadcha}}}{(1 + x)^3} + \frac{A_{\text{quadind}}}{(1 + x)^5} \right) - 1 \right) dx
\]  

(5.61)

where \( A_{\text{indind}} \) is defined as the interaction parameter for induced dipole – induced dipole interaction

\[
A_{\text{indind}} = \frac{3}{4} \left( \frac{2H_{a,j}}{\pi \sigma^3 pc T_{\text{Ads}}} \right) T_C
\]  

(5.62)

The integral increases very strongly with increasing distance \( x \), for small values of \( x \) it reaches a limit. In this work it is recommended to use a limiting value of 2 for \( x \). The integral itself is not analytically solvable. It is not possible to introduce a regression function because it is a three-dimensional problem. Nevertheless, with commercial software like MathCAD numerical values for the *Henry* Loading IL can be evaluated. This value can be transformed to the *Henry* coefficient due to

\[
He = \frac{IL \cdot \sigma_{i,j} \cdot S_{\text{BET}}}{R \cdot T_{\text{ads}}}
\]  

(5.63)

Therefore, it is possible to compare the theoretical a priori calculated *Henry* coefficient with experimental data. The value pairs should lie on a diagonal in a coordinate system with the experimental *Henry* values as the \( x \)-axes and the calculated ones as the \( y \)-axes. The quality of the model will be discussed in Chapter 7.
5.4. Calculation methods for the Henry coefficient

5.4.1. Henry coefficients from experiments and literature

The Henry coefficients from experiments were derived in this work by applying the Langmuir and Toth formulae for adsorption, in this study the equations (3.109) and (3.119).

The proposed Langmuir method is a graphical method from which the Henry coefficient can be obtained by regressing the transformed data by a linear curve. The intercept of this linear curve with the y-axis is indirectly proportional to the Henry coefficient. In this plot the y-axis shows the ratio of the equilibrium pressure $\frac{p}{n}$ in Pa/(mol*kg) whereas the x-axis shows the equilibrium pressure $p$ itself in Pa. The data were analysed by using commercial programs.

The same experimental data have also been analysed by the Toth equation (3.119) due to an analytical fitting method because a three parameter isotherm cannot be represented by a two dimensional graph. Model parameters are obtained using the non-linear least square method of Margules. The parameters are optimised based on the minimum sum of square error given by

$$ss = \sum_{i=1}^{NP} \left( \frac{n_{\text{model}}}{n_{\text{experiment}}} \right)^2 + \sum_{i=1}^{NP} \left( n_{\text{model}} - n_{\text{experiment}} \right)^2$$  \hspace{1cm} (5.64)

where $ss$ is the sum of square errors and $NP$ the number of data points from the experiment.

In many literature essays Henry coefficients are tabulated or given as a function of temperature and heat of adsorption. If not, adsorption isotherms were analysed by the two mentioned methods of Langmuir and Toth. In some of the essays the authors did not tabulate the data points of equilibrium pressure and loading. In such cases the adsorption graphs were scanned and the data points were quantified by the graphical program Origin®.
Theoretical Henry coefficients

Theoretical Henry coefficients have been calculated by using the derived equations (5.59) and (5.61) in the commercially available mathematic program MathCAD® (Version 13, Mathsoft Engineering & Education, Inc.). This program has a Maple kernel to calculate mathematical equations. Equation (5.65) was used in MathCAD® to calculate the dimensionless Henry coefficient of Z different adsorption pairs with

\[
IL := \sum_{i=0}^{Z} \left( \frac{A_{\text{QUADIND}}_i}{f_{\text{quadind}}} \cdot \exp\left(\frac{-0.75A_{\text{INDIND}}_i}{(1 + x)^5} + \frac{A_{\text{DIPIND}}_i}{f_{\text{dipind}}} + \frac{A_{\text{QUADCHA}}_i}{f_{\text{quadcha}}} + \frac{A_{\text{DIPCHA}}_i}{f_{\text{dipcha}}} + \frac{A_{\text{INDCHA}}_i}{f_{\text{indcha}}} \right) - 1 \right) \ dx
\]

(5.65)

where the interaction parameters \( A_{ij} \) are one-dimensional vectors with length of \( Z \) and \( x \) is the reduced distance as in equation (5.30). The result IL, also a vector with length of \( Z \), is written back to a calculation sheet. The unknown coefficients \( f_{ij} \) have been determined by theoretical and experimental considerations and will be discussed in Chapter 7. They can be interpreted as potential factors of the interaction parameters \( A_{ij} \). At a first approach it is expected that these potential factors should be close to unity or even \( f_{ij} = 1 \). However, experimental results show that in the case for interactions which refer to the electrical charge \( q \) derived in the Sections 5.3.2, 5.3.4 and 5.3.6 the factors are only close to unity. All other factors are equal to 1. The reasons for this behaviour may be the fact that the distance of the different atoms and their angles with respect to the dipole axis of the adsorptive molecule differs from atom to atom. Therefore all average values depend on these distances and angles. For instance, equation (5.49) is valid for freely rotating molecules. This may not be true for molecules adsorbed in the cage of a zeolite. Israelachvili [21] has shown that calculations with the objective to average distances and angles are problematic. It is assumed that these average values can be calculated by complex integrals. In Chapter 7 the \( f_{ij} \) are derived from theoretical considerations and experimental results. They will be discussed later in more detail.
6. Prediction of Isotherms for $p \rightarrow \infty$ (Saturation)

The a priori prediction of adsorption isotherms based only on the properties of the adsorptive and the adsorbent molecules is a challenging goal. In this Chapter a new model will be introduced which enables the prediction of the isotherm from the *Henry* to the saturation region for *Hamaker* dominant adsorption pairs and for systems where the adsorptive is polar and the adsorbent is heterogeneous with respect to energy.

Examples for the *Hamaker* dominant case are the adsorption of an unpolar gas like an alkane on active carbon or any molecular sieve or the adsorption of polar adsorbatives on any energetic homogenous adsorbent. Furthermore the fourth case is the adsorption of any polar molecule like methanol on energetically heterogeneous microporous solids like zeolite NaY.

The idea of the presented new model is that any isotherm of type I has two boundary conditions for the two variables loading $n$ and partial pressure $p$. The first boundary condition is that in the *Henry* region the loading and the equilibrium pressure have a constant ratio, equal to the *Henry* coefficient. The second boundary condition is that in the saturation region the slope of the curve $n=f(p)$ becomes zero. With a differential equation for the variables the intermediate range it is possible to calculate the whole adsorption isotherm mathematically.

In this model it is assumed that a narrow relationship between the relevant interaction energies and the *Henry* coefficient exists. The saturation is calculated only in dependence on the properties of the adsorptive and the adsorbent.

In Chapter 7 the quality of this new model will be validated by comparing the predicted isotherms with data from the literature and also with data from own adsorption experiments.
6.1. Differential form

The maximum loading \( n_\infty \) for \( p \to \infty \) is given when the micropore volume is completely filled with adsorbate which has the molar volume \( \beta(T) \):

\[
n_\infty = \frac{v_{\text{micro}} P_{\text{adsorb}}}{M_i} = \frac{v_{\text{micro}}}{\beta(T)}
\]

(6.1)

The relationship between

- the pore filling degree \( n_s^* = \frac{n}{n_\infty} \)
- the number \( N \) of molecule layers
- the microporosity parameter \( \frac{S_{\text{BET}} \sigma_j}{\nu_{\text{micro}}} \) and
- the adsorbate parameter \( \frac{N_A \sigma_i^3}{\beta(T)} \)

can be described by

\[
n_s^* \equiv \frac{n}{n_\infty} = N \cdot \frac{S_{\text{BET}} \sigma_j}{\nu_{\text{micro}}} \cdot \frac{\beta(T)}{N_A \sigma_i^3}
\]

(6.2)

The microporosity parameters of the adsorbents investigated in this work are in the range \( 0.60 < \frac{S_{\text{BET}} \sigma_j}{\nu_{\text{micro}}} < 1 \), see as examples tables 7.4, 7.5 and 7.6. Nearly all adsorptives with molar masses above \( M = 16 \) kg/kmol valid for methane have adsorbate parameters in the range \( 0.5 < \frac{N_A \sigma_i^3}{\beta(T)} < 0.75 \) at a temperature of 300 K, see as examples tables 7.4, 7.5 and 7.6. This means that the maximum number \( N_{\text{max}} \) of
molecular layers is between $N_{\text{max}} = 0.3$ up to $N_{\text{max}} = 1$ for the pore filling $n_s = \frac{n}{n_{\infty}} = 1$ which corresponds for a complete filling of all micropores.

According to Mersmann [122] the Henry range of an adsorption isotherm is finished when the number of layers, $N_{\text{He}}$, assumes approximately the value 0.1. This means that the borderline between the Henry range and the transition range can be expected between $\left(\frac{n}{n_{\infty}}\right)_{He} = 0.1$ and $\left(\frac{n}{n_{\infty}}\right)_{He} = 0.2$. In the loading range $\left(\frac{n}{n_{\infty}}\right)_{He} \leq \left(\frac{n}{n_{\infty}}\right)_{He}$ the adsorption places with the highest energies will be occupied.

Therefore, the interaction energy is smaller than the overall energy $-\frac{\Phi(z)}{kT_{\text{ads}}}$ in equation (5.60) in the case $\left(\frac{n}{n_{\infty}}\right) > \left(\frac{n}{n_{\infty}}\right)_{He}$. It can be shown that the energy $-\frac{\Phi_{\text{indind}}}{kT_{\text{ads}}}$ is at least 50 % up to 93 % of the overall energy.

It is further assumed that in the transition range between the Henry and the saturation region the Hamaker energy is dominant in comparison to other possible potentials. According to Braun [4] and Hirschfelder et. al. [19] Hamaker potentials are long-range interactions. For the first layer of adsorbate molecules on the solid surface the electrostatic potentials have to be taken into account as done for the calculating of the Henry coefficient. In the second layer the Hamaker energy is dominant because of its long-range attraction compared to the electrostatic forces.

Furthermore, the reduction of the interaction energy is caused by the presence of adsorbate molecules and by their distance from the surface molecules of the adsorbent. According to equation (5.24) the energy is reduced by a factor $\left(\frac{1}{2}\right)^3 = 0.125$ for adsorptive molecules in the second layer. Therefore, the slope $\frac{d(\ln n)}{d(\ln p)}$ of an isotherm decreases with an increasing pore filling $\left(\frac{n}{n_{\infty}}\right)$ and increasing interaction energy. This is demonstrated in figure 6.1 where the pore filling of some adsorptives
is plotted against the pressure. The higher the interaction energy the smaller is the pressure valid for leaving the *Henry* range and entering the transition range.

Figure 6.1: Adsorption isotherms on active carbon coal, fitted with Langmuir (methane/ac and ethane/ac) and Toth (acetone/ac and methanol/ac).

Consequently, adsorptives with high 

\[
\frac{T_c}{T_{ads}} \left( \frac{Ha_j}{\sigma_j p_c} \right)^{\frac{1}{2}}
\]

data lead to a wide transition range over several orders of magnitude of the pressure and their mean slope \( \frac{d(ln n)}{d(ln p)} \) in the transition range is small. This slope assumes zero for \( n_s \rightarrow 1 \) (saturation). All this ideas lead to the following differential equation which fulfils these requirements [122]:

\[
\frac{d(ln n)}{d(ln p)} = \frac{dn}{dp} \frac{1}{n} = \frac{1}{1 + C T_{r,ads} \left( E_{Ha}^* \right)^{\frac{1}{2}} \left( \frac{n}{n_\infty} \right) \left( \frac{n}{n_\infty} - 1 \right)}
\]

(6.3)

with \( \frac{d(ln n)}{d(ln p)} = 1 \) for \( n \rightarrow 0 \) and \( \frac{d(ln n)}{d(ln p)} = 0 \) for \( n \rightarrow n_\infty \).
It is assumed that C is a constant, and its order of magnitude can be evaluated from the condition that the expression \( C T_{r, \text{ads}} \left( E_{Ha}^* \right)^{1/2} \left( \frac{n}{n_\infty} \right) \left( \frac{n}{n_\infty} \right) \) must be noticeable compared to 1 (say 0.1) when leaving the Henry range. In this work C = 0.55 \times 10^{-3}.

Some parameters in equation (6.3) are dimensionless numbers and can be defined as

\[
T_{r, \text{ads}} = \frac{T_{\text{ads}}}{T_c} 
\]

(6.4a)

\[
E_{Ha}^* = \frac{Ha_j}{\sigma_j \rho_c} 
\]

(6.4b)

where \( T_{r, \text{ads}} \) is the reduced adsorption temperature and \( E_{Ha}^* \) the reduced Hamaker energy. The loading \( n_\infty \) is equal to the saturation loading when the micropore volume \( v_{\text{micro}} \) is completely filled with adsorbate of the density \( \rho_{\text{adsorb}} \) and can be calculated by equation (6.1) where \( v_{\text{micro}} \) is in m\(^3\)/kg\(_{\text{adsorbent}}\), the density \( \rho_{\text{adsorb}} \) in kg\(_{\text{adsorbate}}\)/m\(^3\) and the molar mass \( M_i \) in kg\(_{\text{adsorbate}}\)/mol\(_{\text{adsorbate}}\).

The calculation of the adsorbate density, especially in the supercritical region, is afflicted with uncertainties because the physical state of an adsorbed molecule cannot be described definitely. In this work, if no data for the density of the liquid was available, the ratio of molar mass of the adsorbate and adsorbate density is calculated by the molar volume of the adsorbate \( \beta \) [36] which depends on the adsorption temperature \( T_{\text{ads}} \). The molar volume is inter- and extrapolated between the molar volume of the adsorptive molecule at the normal boiling point \( v_b \) and the van-der-Waals volume \( v_{vdW} \) [36]. It is

\[
\frac{M_i}{\rho_{\text{adsorb}}} = \beta(T_{\text{ads}}) = v_b + \left( \frac{T_{\text{ads}} - T_b}{T_c - T_b} \right) (v_{vdW} - v_b) 
\]

(6.5)
where \( T_b \) is the normal boiling temperature of the adsorptive. \( T_b \) and the normal molar volume of the adsorptive \( v_b \) are tabulated for many cases in the literature [106]. For any other case the normal molar volume in m\(^3\)/mol can be calculated by the method of Tyn and Calus [106] with

\[
v_b = 0.285 \times 10^{-6} \times v_c^{1.048}
\]

(6.6)

where \( v_c \) is the critical volume of the adsorptive in cm\(^3\)/mol, see figure 6.2.

Figure 6.2: Normal molar volume of the adsorptive in dependence of the critical volume [106].

The van-der-Waals volume \( v_{vdW} \) can be expressed by equation (3.29). The saturation loading \( n_\infty \) is now

\[
n_\infty = \frac{v_{micro}}{\beta(T_{ads})}
\]

(6.7)

The ratio of the loading \( n \) to the saturation loading \( n_\infty \) is defined as the saturation degree \( n_s \) with

\[
n_s = \frac{n}{n_\infty} = \frac{n M_i}{v_{micro} \rho_{adsorb}} \quad \text{or}
\]

(6.8)
\[ n^*_s = \frac{n}{n_\infty} = \frac{n \beta(T)}{v_{\text{micro}}} \]  

(6.9)

Equation (6.3) can be rewritten with the definition

\[ B = C \frac{T_{\text{ads}}}{T} \left( \frac{Ha_j}{\sigma_j^3 p_c} \right)^{\frac{3}{2}} \]

(6.10)

which is independent of the loading \( n \) and the pressure \( p \) to

\[ d(\ln n) \left( 1 + B \left( \frac{n/n_\infty}{1 - n/n_\infty} \right) \right) = d(\ln p) \]

(6.11)

6.2. Integrated form with boundary conditions

Generally, three cases can be distinguished with respect to the slope \( \frac{d(\ln n)}{d(\ln p)} \) of an adsorption isotherm:

- \( \frac{d(\ln n)}{d(\ln p)} = 1 \) (dilute or Henry range)  
  (6.12)

- \( \frac{d(\ln n)}{d(\ln p)} = 0 \) (saturation range) and
  (6.13)

- \( \frac{d(\ln n)}{d(\ln p)} = g(f(n^*_s, T_{\text{r-ads}}^*, E_\text{Ha}^*, n^*_S)) \)  
  (6.14)

6.2.1. The dilute region

The first case is the region where the loading \( n \) is much smaller than the saturation loading \( n_\infty \), so

\[ n \ll n_\infty \]  

(6.15)
The differential equation (6.11) reduces to equation (6.12). The integration of the differential equation (6.12) leads to

\[
\int d(\ln n) = \int d(\ln p) \quad \text{or} \quad (6.16)
\]

\[
\ln n = \ln p + \ln \text{Const.} \quad (6.17)
\]

The integration constant \(\text{Const.}\) can be interpreted as the Henry coefficient:

\[
\ln \text{Const.} = \ln \text{He} \quad (6.18)
\]

It follows that

\[
\ln \left( \frac{n}{\text{He} p} \right) = 0 \quad \text{or} \quad (6.19)
\]

\[
n = \text{He} p \quad (6.20)
\]

which is known as Henry’s law. Some authors doubt that a real Henry region exists with respect to the more or less degree of heterogeneity of the adsorbent surface. However, dealing with chemical engineering predictions the assumption of a Henry range is reasonable and helpful.

**6.2.2. The saturation region**

In the saturation region the slope of the loading \(n\) relative to the equilibrium pressure does not change significantly. The limit of the differential equation (6.3) is for \(n \to n_\infty\)

\[
\lim_{n \to n_\infty} \frac{d(\ln n)}{d(\ln p)} = \lim_{n \to n_\infty} \frac{1}{1 + C \left( \frac{T_c}{T_{\text{ads}}} \right) \left( \frac{Ha_j}{\sigma_j p_c} \right)^{\frac{1}{2}} \left( \frac{n}{n_\infty} \right) \left( \frac{1 - n}{1 - n/n_\infty} \right)} = 0 \quad (6.21)
\]
or

\[ d(\ln n) = 0 \quad \text{or} \quad (6.22) \]

\[ n = \text{const.} = n_\infty \quad \text{(6.23)} \]

### 6.2.3. The general case

In the regime between the Henry and the saturation region the differential equation (6.11) has to be solved. It follows with

\[ d(\ln n) = \frac{dn}{n} \quad \text{(6.24)} \]

the integral form

\[ \int d(\ln n) + B \int \frac{n/\n_\infty}{1 - n/\n_\infty} \frac{dn}{n} = \int d(\ln p) \quad \text{or} \quad (6.25) \]

\[ \ln n - B \ln\left(1 - \frac{n}{n_\infty}\right) = \ln p + \ln He \quad \text{(6.26)} \]

Equation (6.26) can be rewritten to

\[ \ln\left(\frac{He \ p}{n}\right) = -B \ln\left(1 - \frac{n}{n_\infty}\right) = \ln\left(1 - \frac{n}{n_\infty}\right)^{-B} \quad \text{(6.27)} \]

It follows the adsorption isotherm description for the general case (see figures 6.3 and 6.4) with
\[
\frac{He}{n} p = \left( \frac{1}{1 - \frac{n}{n_\infty}} \right)^b \quad \text{or} \quad (6.28):
\]

\[
p = \frac{n}{He} \left( \frac{1}{1 - \frac{n}{n_\infty}} \right)^b \quad (6.29)
\]

7. Results and Discussion

7.1. New experimental results

The experiments carried out for measurements are described in the appendix B2. Experiments were carried out in Garching and Leipzig.

7.1.1. Adsorption isotherms

Adsorption isotherms of methanol and dichloromethane were measured on zeolites MS5A, NaX and NaY. These systems were chosen to expand literature data with experimental data in the case of adsorption of polar molecules or such with high polarisabilities on energetic heterogeneous sorbents. The experiments were carried out in the pressure range from 0.1 Pa to saturation pressure of the adsorptive at room temperature. Figure 7.1 shows adsorption isotherms of methanol on several zeolites. Figure 7.2 shows adsorption isotherms of dichloromethane on the same zeolites. The temperatures ranged from 44°C to 47°C.

As can be seen in figure 7.1 methanol has the highest adsorption affinity with NaY followed by MS5A and NaX, which seem to have the same adsorption attraction to methanol. NaY was pure crystalline, MS5A and NaX have been used as industrial pellets with binder amount. The MS5A zeolite was grated to powder, pressed together and then broken to small pieces for the glass crucible. Adsorption was repeated for this modified molecular sieve. The experiment shows that there is some diffusion resistance when adsorbing into industrial pellets with binder amount. For the theoretical calculations only the data of the crystals and grated pellets were taken. Reliable data from the Garching experiments begin at 0.1 Pa, the reliable data from Leipzig begin at 10 to 100 Pa. The saturation loading for methanol on the examined zeolites was in the magnitude of 6 to 6.5 mol/kg. This is in good agreement with the theory of micropore filling as will be shown later. The Henry region of methanol adsorption on zeolites ends at high loadings of approximately 3 mol/kg or 10 Pa,
respectively. In the experiments the Henry region could be reached very well down to pressures of 0.1 Pa.

![Graph showing methanol adsorption on zeolites NaY, MS5A, and NaX](image)

**Figure 7.1:** Methanol adsorption on zeolites NaY, MS5A, and NaX.

Dichloromethane adsorption was conducted with crystal NaY and grated MS5A zeolite pellets and additionally with NaX zeolite. The Henry region ends at approximately 2 Pa for MS5A and 10 Pa for NaY. The saturation loading is in the range of approximately 3.5 mol/kg, less than methanol because of the higher molar mass of approximately 84 kg/kmol. Henry coefficient calculations will be compared later regarding to Langmuir and Toth regressions.

With this experiments it could be shown that the Henry region and the saturation region of solvents with moderate dipole moments of approximately 1.5 debye on zeolites can be measured with gravimetric adsorption methods.
7.1.2. Comparison of Langmuir and Toth regression quality

In this Section the experimental data are fitted with both Langmuir and Toth adsorption isotherms. Figure 7.3 shows the adsorption of methanol on NaY and in figure 7.4 the adsorption equilibrium of dichloromethane on MS5A zeolite is shown. In both cases the Toth isotherm delivers better fits to the experimental data than the Langmuir isotherm. The standard deviation is 8.1 % for Toth and 17.3 % for Langmuir in the case of methanol adsorption on NaY. Furthermore the standard deviation is 3.8 % for Toth and 5.8 % for Langmuir in the case of dichloromethane adsorption on MS5A. In Table 7.1 the standard deviations for the experimental data are listed. On the basis of this table it was decided to calculate the Henry coefficient with Toth regression which fitted better to the data. Toth parameters \( n_{\text{max}} \), \( K_T \) and \( m \) and Langmuir parameters \( n_{\text{mon}} \) and \( K_L \) are explained in Chapter 3.

7.1.3. BET surface and micropore volume

The specific surface of the solids has been measured by adsorption of nitrogen at 77 K. Figure 7.5 shows the BET isotherm for zeolite NaY in the linear form of equation (3.7) with the relative pressure interval from 0.05 to 0.30. The intercept point of the linear fit to the experimental data has the value $b = -0.00297 \text{ kg/mol}$ and the gradient $m$ is equal to 0.152 kg/mol. With equation (3.5) the monolayer loading of the BET isotherm $n_{\text{mon}}$ is equal to 6.72 mol/kg. The BET constant can be calculated by equation (3.6) and it is $c = -50.05$. With equation (3.7) and the occupied area of one nitrogen molecule $a_{\text{mol(N}_2\text{)}} = 0.162*10^{-18} \text{ m}^2$ at 77.4 K it is $S_{\text{BET}} = 655400 \text{ m}^2/\text{kg}$ for NaY zeolite. The other solids have been measured with the same method.

The micropore volume of the adsorbents were determined by the t-plot method. The data for the evaluation of the micropore volume was taken from the same interval as for the BET method, e.g. in the relative pressure interval 0.05 to 0.30. For NaY the micropore volume has been calculated to $v_{\text{micro}} = 0.272*10^{-3} \text{ m}^3/\text{kg}$. 
7.2. Prediction of isotherms

7.2.1. Henry coefficient predictions

Henry coefficients were calculated with the new method (equations (5.15) and (5.65)) explained in Chapter 5 and compared with data from the literature and with own experimental data, respectively. The model quality is exemplarily discussed on zeolites MS5A, MS4A, NaY and NaX.

As mentioned in Chapter 5 the potential factors for charge interactions were calculated based on theoretical assumptions and experimental results. For induced dipole interactions (indind, dipind and quadind) where no charge is involved on the solid side it is assumed that

\[ f_{\text{indind}} = f_{\text{dipind}} = f_{\text{quadind}} = 1 \]  

(7.1a)

For charge involved interactions (indcha, dipcha, quadcha) it is assumed in first approximation that
\[ f_{\text{indcha}} = f_{\text{dipcha}} = f_{\text{quadcha}} = f_{\text{charge}} \cdot \left( \frac{Al}{Si} \right) \quad \text{(7.1b)} \]

where \( \left( \frac{Al}{Si} \right) \) is the aluminium to silicon ratio of adsorbent \( j \) and \( f_{\text{charge}} \) the potential factor for charge involved interactions. \( \left( \frac{Al}{Si} \right) \) is different for every zeolite. The parameter \( f_{\text{charge}} \) is equal to 1.35 for every microporous adsorbent. For MS5A it is \( \left( \frac{Al}{Si} \right) = 1 \), therefore \( f_{\text{indcha}} \) is assumed to be 1.35. It will be shown next that this first approximation is very sufficient for charge interactions. In order to test the validity and the accuracy of the new model the Henry coefficients were calculated for several adsorption cases of gases on zeolites and compared with experimental values. With this method it was possible to determine the unknown potential factors \( f_{i,j} \) in equation (5.65).

- According to the theoretical and experimental results of Maurer [26] the induced dipole – induced dipole potential for the zeolites also were calculated with a potential factor \( f_{\text{indind}} = 1 \).

- Methane has no dipole moment (\( \mu_i = 0 \)), no quadrupole moment (\( Q_i = 0 \)) and a polarisability of \( \alpha_i = 3.0 \times 10^{-40} \) \((C^2*m^2)/J\). Adsorption on MS5A (\( S_{\text{BET}} = 600000 \) \(m^2/kg\)) at 293 K was examined regarding to [35]. The experimental Henry coefficient is tabulated [35] as \( 8.8 \times 10^{-6} \) mol/(kg*Pa). With \( f_{\text{indind}} = 1 \) in equation (5.62) the calculated Henry coefficient is \( 7.93 \times 10^{-6} \) mol/(kg*Pa) if the parameter \( f_{\text{indcha}} \) is calculated with equation (7.1b) to 1.35. It will be shown later that the factor \( f_{\text{indcha}} \) calculated by equation (7.1b) is adequate with respect to isotherms investigated in this study.

- Ethene has no dipole moment (\( \mu_i = 0 \)), a quadrupole moment \( Q_i = 1.44 \times 10^{-39} \) \(C*m^2\) and a polarisability \( \alpha_i = 3.0 \times 10^{-40} \) \((C^2*m^2)/J\). It adsorbs on NaY (\( S_{\text{BET}} = 500000 \) \(m^2/kg\)) at 305 K with a Henry coefficient of \( 2.56 \times 10^{-3} \) mol/(kg*Pa) [117]. NaY has an aluminium to silicon ratio of \( \left( \frac{Al}{Si} \right)_{\text{NaY}} = 0.41 \). With known potential factors \( f_{\text{indind}} = 1 \) and \( f_{\text{indcha}} = 1.35 \times 0.41 = 0.554 \) and an assumed potential factor \( f_{\text{quadind}} = 1 \) the calculated Henry coefficient is \( 7.0 \times 10^{-4} \) mol/(kg*Pa).
Carbon dioxide has a small dipole moment \( \mu_i = 2.34 \times 10^{-30} \text{ Cm} \), a strong quadrupole moment \( Q_i = 1.5 \times 10^{-39} \text{ C}^2\text{m}^2 \) and a polarisability \( \alpha_i = 2.9 \times 10^{-40} \text{ (C}^2\text{m}^2)/\text{J} \). It adsorbs on MS4A (\( S_{\text{BET}} = 350000 \text{ m}^2/\text{kg} \)) at 298 K with a Henry coefficient of \( 1.36 \times 10^{-3} \text{ mol/(kg*Pa)} \) [22]. In adsorptive molecules with strong quadrupole moments two dipoles in counterdirection can exist [132]. Furthermore a strong quadrupole moment can induce a dipole moment \( \mu_j \) in the adsorbent molecule (see chapter 5 in this thesis). The order of magnitude of the ratio \( \frac{Q_i}{\mu_i \sigma_i} \) of many polar adsorptive molecules is \( \approx 1 \) or \( \mu_i \sigma_i = \mu_i \sigma_{i,j} = Q_i \). With respect to this simple relationship it may be reasonable to introduce the factor \( 2\sigma(2)^2 = 8 \) in equation (5.57) in order to take into account the phenomena described above:

\[
\Phi_{\text{quadcha}}(x) = \frac{8}{240} \frac{Q_i^2 s_{\text{cations}}^2 \rho_{\text{lat}}}{\pi e_i^2 e_j^2 (kT_{\text{ads}})^2} \frac{1}{\sigma_{i,j}^3 (1 + x)^3} \quad (7.1c)
\]

An introduction of this factor 8 leads to the result that the charge potential factor \( f_{\text{charge}} \) seems to have the value 1.35 for all zeolites. With an aluminium to silicon ratio of 1 for MS4A it follows \( f_{\text{quadcha}} = 1.35 \) and a calculated Henry coefficient of \( 3.4 \times 10^{-3} \text{ mol/(kg*Pa)} \).

Ammonia has a strong dipole moment \( \mu_i = 5.0 \times 10^{-30} \text{ Cm} \), a strong quadrupole moment \( Q_i = 8.7 \times 10^{-40} \text{ C}^2\text{m}^2 \) and a relative small polarisability \( \alpha_i = 3.1 \times 10^{-40} \text{ (C}^2\text{m}^2)/\text{J} \). It adsorbs on NaY (\( S_{\text{BET}} = 500000 \text{ m}^2/\text{kg} \)) at 373 K with a Henry coefficient of \( 2.82 \times 10^{-4} \text{ mol/(kg*Pa)} \) [118]. With a potential factor \( f_{\text{charge}} = 1.35 \) and an aluminium to silicon ratio of 0.41 the Henry coefficient can be calculated to \( 2.14 \times 10^{-4} \text{ mol/(kg*Pa)} \).

Methanol has a big dipole moment \( \mu_i = 5.7 \times 10^{-30} \text{ Cm} \), a small quadrupole moment \( Q_i = 4.3 \times 10^{-40} \text{ C}^2\text{m}^2 \) and a small polarisability \( \alpha_i = 3.7 \times 10^{-40} \text{ (C}^2\text{m}^2)/\text{J} \). It adsorbs on the zeolite NaY (\( S_{\text{BET}} = 655400 \text{ m}^2/\text{kg} \)) at 318 K with a Henry coefficient of \( 6.71 \times 10^{-1} \text{ mol/(kg*Pa)} \). The predicted Henry coefficient is \( 2.5 \times 10^{-1} \text{ mol/(kg*Pa)} \) if a potential factor \( f_{\text{dipind}} = 1 \) is assumed.

* Another way for deriving the factor 8 is explained in the appendix C.
The potential factors as shown above were taken to calculate the adsorption of arbitrary gases on any microporous solid. The results are explained in the following.

Figure 7.6 and 7.7 show Henry coefficients of zeolite MS4A with the adsorptives ammonia, carbon dioxide, carbon monoxide, methane, propane, hexane, helium, nitrogen, oxygen and benzene on zeolite MS4A. In figure 7.6 the theoretical Henry coefficients were calculated on basis of the induced dipole- induced dipole potential.

Figure 7.6: Henry coefficients for adsorption of gases on MS4A zeolite on basis of only induced dipole – induced dipole interactions (table 7.2).

The next figure 7.7 is based on all potentials taken into account as described in Chapter 5 and on the potential factors. Besides benzene and hexane the prediction works very well as can be seen in table 7.2. The van-der-Waals diameters of benzene and n-hexane are 4.56 E-10 m and 5.18 E-10 m, respectively. It seems that these
molecules are too big for the effective micropore opening of MS4A. The model predicts Henry coefficient values between 3 and 5 magnitudes larger than the experimental ones. Although sterical effects like these cannot be represented the new model works very well over 4 orders of magnitudes in the case of the MS4A adsorption examples. It is interesting to mention that in the case of NH₃ for instance the loading is by a factor $10^3$ higher than calculated with induced dipole – induced dipole interactions only.

The tested adsorptives cover different types of molecules with different polar properties. Noble gases like helium have no dipole moment, no quadrupole moment and small polarisabilities. Alkanes like methane, propane and hexane have no dipole moment, small quadrupole moments and intermediate polarisabilities. Carbon monoxide and carbon dioxide have small and medium dipole moments, respectively, large quadrupole moments and small polarisabilities. NH₃ has a relative big dipole moment of 1.5 debye, a big quadrupole moment of $8.67 \times 10^{-40}$ C*m² but only a small
polarisability of $3.13 \times 10^{-40} \text{ C}^2 \text{m}^2/\text{J}$.

**Figure 7.7**: Henry coefficients for adsorption of gases on MS4A zeolite (table 7.2).

</tbody>
</table>
As second example for energetic heterogeneous adsorbents figures 7.8 and 7.9 show the comparison of experimental and calculated Henry coefficients for the zeolite NaX. Table 7.3 lists the deviations in percent. Besides ammonia, methanol is a molecule with a high dipole moment of 1.7 debye. The deviation of the calculated Henry coefficient from the experimental one is only 41 %, whereas its deviation is 290432 % when calculated on the basis of the induced dipole – induced dipole interaction only. A second example for polar molecules is naphthalene C_{10}H_{8}. It has a high quadrupole moment of 4.5*10^{-39} \text{ Cm}^2 and a high polarisability of 1.94*10^{-39} \text{ C}^2\text{m}^2/\text{J} but no dipole moment. The deviation in figure 7.9 is 56 % whereas in figure 7.8 it is 11579 %. These data prove the efficiency of the new model very clearly. It is interesting to note that the largest deviations are observed in the case of adsorptives with strong quadrupole moments (NH_{3}, CO, CO_{2}, C_{2}H_{4}).

Figure 7.9: Henry coefficients for adsorption of gases on NaX zeolite (table 7.3).

7.2.2. Isotherm predictions

In Chapter 6 a new model was introduced to calculate the whole adsorption isotherm from the linear region until saturation. In this Section the model will be verified based on literature and experimental data. Henry coefficients of the model are calculated as shown in Chapter 6 and verified in Section 7.2.1. The saturation data which is the second main boundary condition is tabulated in tables in addition to the graphic presentation.

In figure 7.10 the prediction of isotherms for active carbon coal is shown. Active carbon coal is an energetic homogeneous adsorbent. In this case the adsorption attraction of arbitrary gases is dominated by the reduced Hamaker energy.
Active carbon coal can be modelled very well with the prediction theory of Chapter 6. It is assumed that the parameter $C$ is a constant with $C = 0.55 \times 10^{-3}$. This is verified also in Section 7.3.3. The calculated Henry coefficients of various types of molecules differ at most 19% (in the case of carbon dioxide) from the experimental data. Also the saturation region is modelled very well. It seems that the new model can cover any arbitrary gas if adsorbed on energetic homogenous adsorbents like active carbon.

**Figure 7.10:** Experimental and predicted adsorption isotherms of active carbon coal. Experimental data are for nitrogen (303.15 K, −), methane (303.15 K, ▲), carbon dioxide (303.15 K, ♦), propane (298 K, ■) and methanol (298.15 K, •), −, -- calculated.

In order to test the validity and the accuracy of the new model adsorption isotherms over the entire range from the Henry region up to saturation have been calculated for special adsorptives on zeolites.

**Figure 7.11**: Adsorption of n-hexane on silicalite-1 at 298 K [126]. –, -- calculated.
Figure 7.11 shows an $\alpha_i$-dominant adsorption case of n-hexane on silicalite-1 [126]. n-hexane possesses a high polarisability but zero polarities. Silicalite-1 has no cations in its structure, therefore it has no charge involved interactions. The example shows that the $\alpha_i$-dominant adsorption case is covered very well by the model.

An additional approach for Hamaker-dominant systems will be presented here. In figure 7.12 the dimensionless loading $n/(He*p)$ is plotted versus a dimensionless term which contains the loading $n$, the saturation loading $n_\infty$, the critical data $p_c$ and $T_c$ of the adsorptive and the Hamaker energy $H_{ai}$. The diagram is valid for Hamaker-dominant systems (for instance activated carbon as adsorbent). The plot is similar to the diagram published in [27] as figure 3.22. However, in the figure of [27] the expression of $(He*p)/n$ is plotted versus an abscissa expression with the number of molecule layers $N = \frac{N_i \sigma_i^2}{S_{BET}} n$. In figure 7.12 the term $\left(1 - \frac{n}{n_\infty}\right)$ can be interpreted as the fraction of the micropore volume not occupied by the adsorbate yet. Furthermore, the expression is powered by the exponent 2/3 in order to obtain the Hamaker energy $H_{ai}$ with the exponent one instead of 3/2 [27]. The straight line in figure 7.12 is supported by experimental results of $N_2$, $CH_4$, $C_3H_8$, $C_3H_6$, $C_6H_{14}$ and ethylacetate adsorbed on activated carbon in the temperature range between 25°C and 93°C and delivers the relationship

$$\ln\left(\frac{n}{He \cdot p}\right) = \left\{-4.36 \cdot 10^{-4} \left(\frac{H_{ai}}{\sigma_j p_c}\right)^{\frac{1}{2}} \frac{T_c}{T_{ads}} \ln\left(1 - \frac{n}{n_\infty}\right)^{\frac{2}{3}}\right\}$$ (7.1)

As can be seen the adsorption isotherm for $T_{ads}$ depends on

- the Henry coefficient $He$,
- the saturation loading $n_\infty$ and on
- the physical properties of the adsorptive and the adsorbent.
Figure 7.12: The dimensionless group \( \frac{n}{He\,p} \) is plotted against the dimensionless group

\[
\left[ -\left( \frac{Ha}{\sigma_j p_C} \right)^{\frac{3}{2}} \frac{T_C}{T_{ads}} \ln \left( 1 - \frac{n}{n_w} \right) \right]^{\frac{1}{2}}
\]

According to Mersmann et.al. [27] the Henry coefficient He can be approximated by

\[
He = \frac{\sigma_{i,j} S_{\text{BET}}}{R T_{\text{ads}}} \exp \left\{ 0.4 \left( \frac{T_C}{T_{ads}} \right) \left( \frac{Ha}{\sigma_j p_C} \right)^{\frac{3}{2}} \right\}
\] (7.2)
In this equation the diameter $\sigma_{i,j}$ and the BET surface are additional parameters. A combination of the two equations (7.1) and (7.2) results in

$$\frac{n}{p} = \frac{\sigma_{i,j} S_{BET}}{R T_{ads}} \exp \left\{ 0.4 \frac{T_c}{T_{ads}} \left( \frac{H_{a_j}}{\sigma_j^3 p_c} \right)^{\frac{1}{2}} \right\}$$

$$\exp \left\{ -4.36 \cdot 10^{-4} \left( \frac{H_{a_j}}{\sigma_j^3 p_c} \right)^{\frac{1}{2}} \frac{T_c}{T_{ads}} \ln \left( 1 - \frac{n}{n_{\infty}} \right) \right\}^{\frac{3}{2}}$$

(7.3)

In figure 7.12 most of the experimental data are located in between the upper and lower line. With respect to the accuracy of an adsorption isotherm calculated by equation (7.3) the Hamaker energy $H_{a_j}$ plays the biggest role. In order to obtain an accuracy of $\pm$ 20% with respect to the entire isotherm an accuracy of approximate $\pm$ 5% of the volumetric Hamaker energy $\left( \frac{H_{a_j}}{\sigma_j} \right)$ is necessary. This may explain some deviations between experimental and predicted data.

Figure 7.13 shows the adsorption of other nonpolar adsorptives on zeolites NaX, NaY and MS5A. Table 7.5 lists the properties of the adsorptives and adsorbents in figure 7.13. The new model is very successful also in predicting adsorption isotherms in the case of nonpolar gases and energetic heterogeneous adsorbents. It has to be mentioned that the success of the model depends strongly on reliable data of the Hamaker energy, the BET surface and the micropore volume of the adsorbent. In the case of zeolites the micropore volume was taken from Kast [24]. The BET surfaces for NaX and NaY in figure 7.13 are average values of literature data. For practical purposes the predicted isotherms are calculated down to the equilibrium pressure 1 Pa. Thus, it is possible to read the Henry coefficient directly from the intercept of the predicted isotherm with the y-axes. For all adsorbents, zeolites and active carbon, the saturation loading seems to be achieved at $10^{18}$ Pa.
Table 7.5: Properties of adsorptives and adsorbents in figure 7.13.

Figure 7.13: Experimental and predicted adsorption isotherms of zeolites. Experimental data are for methane/NaY (298 K, •), methane/NaX (304.5 K, □), ethane/MS5A (313 K, ♦) and propane/MS5A (313 K, ▲). --, -- calculated.
Methanol and ammonia are adsorptives with high dipole moments but rather small polarisabilities. Furthermore the quadrupol moment of ammonia is very high. Especially methanol is an adsorptive which offers the possibility to test the validity of the equations (3) and (4) of figure 5.5. Figure 7.14 shows the adsorption of methanol and ammonia [18] on the zeolites NaY and NaX, respectively.

![Diagram of adsorption (μ-dominant)](image)

**Figure 7.14**: Adsorption of methanol on NaY (318 K, ■) and ammonia on NaX (298 K, ♦). –, -- calculated.

The adsorptives ethene and carbon dioxide are characterised by large quadrupole moments but zero (ethene) or moderate (carbon dioxide) dipole moments and rather moderate polarisabilities. Calculated adsorption isotherms of these adsorptives can be used for testing the validity and accuracy of equations (5) and (6) in figure 5.5. Figure 7.15 shows the adsorption of ethene on MS5A [27] at 303 K and the adsorption of carbon dioxide on NaY [117] at 305 K.
Figure 7.15: Adsorption of ethene on MS5A [27] at 303 K and the adsorption of carbon dioxide on NaY [117] at 305 K. –, -- calculated.

As overall case figure 7.16 and table 7.6 show the adsorption of any polar gases on energetic heterogeneous adsorbents.
Figure 7.16: Experimental and predicted adsorption isotherms of zeolites. Experimental data are for CO$_2$/MS5A (343 K, ■), NH$_3$/NaX (298 K, •), p-xylene/NaY (523K, 7) and CH$_2$Cl$_2$/MS5A (319.35 K, ♦). —, -- calculated.

</table>
The isotherms of figure 7.16 show a highly polar adsorptive (dichloromethane) with a dipole moment of 1.6 debye and three molecules with high polarisabilities and high quadrupole moments (NH₃, p-xylene and CO₂). In the case of p-xylene the saturation loading was calculated with the adsorbate density as given in the literature, $1.08 \times 10^3$ kg/m³ [116] and with equation 6.4.

All the predicted isotherms fit the experimental data very well in the Henry region and the saturation region. By the different systems it is verified that the new model can predict the adsorption of any kind of gas, polar or unpolar, on any kind of microporous adsorbent, energetic homogeneous or heterogeneous. However, in the figure 7.14 the system methanol/NaY show higher loadings than calculated in the transition range.

In the next Sections the parameters of the new model will be verified.

7.3. Model verifications

7.3.1. Refractive index verification

The refractive index is an important parameter for calculating the Hamaker constant of microporous solids like zeolites. In this work the Clausius-Mosotti relation was used to calculate this parameter. In Chapter 3 additional ways were introduced for calculating the refractive index that should be reviewed in comparison to the used method.

As can be seen in equation (3.34) and also as explained in Chapter 3 the Clausius-Mosotti formula describes a border case of the general formula of Marler. In this case the electrical fields of the solid ions do not overlap each other. The other case is described by the formula of Newton-Drude. Here, the overlapping field compensates the Lorentz field exactly. All other cases are between these two border cases, which can be described by the parameter b. So the refractive index can be rewritten as a function of b and the solid parameters.

By introducing a dimensionless solid parameter $P^\ast$ with
\[ P^* = \frac{\alpha_{\text{solid}} N_A \rho_{\text{solid}}}{\varepsilon_0 M_{\text{solid}}} = \frac{3 R_m \rho_{\text{solid}}}{M_{\text{solid}}} \] (7.4)

The refractive index is

\[ n = \sqrt{1 + P^* - \frac{b P^*}{4\pi}} \] (7.5)

The two border cases are for Marler with \( b = 0 \)

\[ n_{\text{Marler}} = \sqrt{1 + P^*} \] (7.6)

and for Clausius-Mosotti with \( b = \frac{4\pi}{3} \)

\[ n = \sqrt{1 + \frac{2 P^*}{3} - \frac{P^*}{3}} \] (7.8)

For MS5A the solid parameter \( P^* \) is equal to \( 9.83 \times 10^{-1} \) with the assumptions made in Chapter 3 and in table 7.7.
Table 7.7: Solid parameters of zeolite MS5A.

<table>

<td>0.983</td>
</tr>
</tbody>
</table>

The function of $n$ in dependence of parameter $b$ (equation 7.5) with the two border cases is plotted in figure 7.17 for zeolite MS5A.

![Figure 7.17: Refractive index of MS5A in dependence on the electronic overlap parameter b.](image-url)
The two border cases result in a refractive index \( n_{\text{min}} = 1.41 \) and \( n_{\text{max}} = 1.57 \). Following the equations in Chapter 3 the dependence of the Hamaker constant \( H_a \) on the refractive index \( n \) is described by

\[
\alpha_{\text{solid}} \sim \frac{n^2 - 1}{n^2 + 2} \quad \text{and} \quad v_0 \sim \frac{1}{\sqrt{\alpha}} \quad \text{and} \quad H_a \sim \beta \sim v_0 \alpha^2 \quad (7.9a)
\]

Therefore, it follows that

\[
H_a \sim \left( \frac{n^2 - 1}{n^2 + 2} \right)^{1.5} \quad (7.9b)
\]

The two border cases lead to a difference of ca. 35 % of the numerical value of the Hamaker constant of MS5A. The maximum value in this work, \( H_{a_{\text{MS5A, max}}} = 7.66 \times 10^{-20} \) J, is calculated with Clausius-Mosotti whereas the minimum value is \( H_{a_{\text{MS5A, min}}} = 5.0 \times 10^{-20} \) J.

The Henry coefficient depends on the Hamaker constant. For further calculations propane adsorption on MS5A is taken as example. The parameters for this case are \( T_c = 369.8 \) K, \( T_{\text{ads}} \) = 343 K, \( \rho_c = 4.25 \times 10^6 \) Pa and \( \sigma_{\text{MS5A}} = 3.8 \times 10^{-10} \) m. It follows with

\[
IP_{\text{min/max}} = T_c \frac{2H_{a_{\text{min/max}}}}{T_{\text{ads}} \pi \sigma_c^2 p_c} \quad (7.10)
\]

and

\[
He \sim IL \quad (7.11)
\]

the percentage difference of the Henry coefficient with

\[
\Delta He(\%) = \frac{IL_{\text{max}} - IL_{\text{min}}}{IL_{\text{min}}} \cdot 100\% = \frac{\exp(p_1 IP_{\text{max}}^{p_2}) - \exp(p_1 IP_{\text{min}}^{p_2})}{\exp(p_1 IP_{\text{min}}^{p_2})} \cdot 100\% \quad (7.12)
\]
For the given example the percentage difference is ca. 550%.

The discussion in the previous section has shown that the theoretical and experimental Henry coefficients differ much less. So it seems that the *Clausius-Mosotti* formula is the right choice for calculating the refractive index and also the Hamaker constant. Another reason is that the *Clausius-Mosotti* formula is described as standard equation in widely accepted literature [6].

### 7.3.2. Dependency on the saturation degree

In Chapter 6 the parameter C in equation (6.3) was assumed to be constant in a first approximation. In this Section a linear dependency of C on the saturation degree \( n_S \) is discussed with

\[
C = a \frac{n}{n_w} + b
\]  
(7.13)

Approximating C between the border values 0.6\( \times 10^{-3} \) and 0.5\( \times 10^{-3} \) for saturation degrees 0 and 1, respectively, the parameters of equation (7.13) are equal to \( a = -0.1 \times 10^{-3} \), \( b = 0.6 \times 10^{-3} \). The differential equation (6.3) turns then to

\[
\frac{d(\ln n)}{d(ln p)} = \frac{dn}{dp} \frac{n}{n_w} = \frac{1}{1 + \left( a \frac{n}{n_w} + b \right) \frac{T_c}{T_{ads}} \left( \frac{H_{a_j}}{\sigma_j p_c} \right)^{\frac{3}{2}} \left( \frac{n}{n_w} \right)^{\frac{3}{2}} \frac{1}{1 - n/n_w}}
\]  
(7.14)

Equation (7.14) can be rewritten with the term \( B' \) defined by

\[
B' = \frac{T_c}{T_{ads}} \left( \frac{H_{a_j}}{\sigma_j p_c} \right)^{\frac{3}{2}}
\]  
(7.15)

into
\[
\begin{align*}
\left(1 + B \left( \frac{n}{n_\infty} \right) \left( a \frac{n}{n_\infty} + b \right) \right) & = d(\ln p) \quad \text{or} \\
\ln n + \int B \left( \frac{n}{n_\infty} \right) \left( a \frac{n}{n_\infty} + b \right) \frac{dn}{n} & = \ln p + \ln He
\end{align*}
\]

(7.16)

This can be reduced to

\[
\ln \left( \frac{pHe}{n} \right) = \int B \left( \frac{a \frac{n}{n_\infty} + b}{1 - \frac{n}{n_\infty}} \right) \frac{dn}{n}
\]

(7.17)

Integration of the right hand side of equation (7.18) leads to

\[
\begin{align*}
\ln \left( \frac{pHe}{n} \right) & = B \left( a \left( - \frac{n}{n_\infty} - \ln \left( 1 - \frac{n}{n_\infty} \right) \right) + b \left( - \ln \left( 1 - \frac{n}{n_\infty} \right) \right) \right) \\
& \quad \text{or} \\
\ln \left( \frac{pHe}{n} \right) & = -B'(a + b) \ln \left( 1 - \frac{n}{n_\infty} \right) - B' a \frac{n}{n_\infty}
\end{align*}
\]

(7.19)

(7.20)

or

\[
\begin{align*}
\ln \left( \frac{pHe}{n} \left( 1 - \frac{n}{n_\infty} \right)^{B'(a+b)} \right) & = -B' a \frac{n}{n_\infty}
\end{align*}
\]

(7.21)

It is therefore
\[ p = \frac{n}{He} \left( \frac{1}{1 - \frac{n}{n_\infty}} \right)^{B'(a+b)} \exp \left( -B'a \frac{n}{n_\infty} \right) \quad (7.22) \]

or in dependence on the saturation degree \( n^*_s = \frac{n}{n_\infty} \) it follows that

\[ p = \frac{n}{He} \left( 1 - n^*_s \right)^{B'(a+b)} \exp \left( -B'an^*_s \right) \quad (7.23) \]

This modified model is verified on the adsorption example carbon dioxide on active carbon, the same example as in figure 7.10. The result is shown in figure 7.18. As can be seen in figure 7.18 there is no significant difference between the two cases. So it is assumed that the parameter C in equation (6.3) is a constant being independent on the saturation degree.
7.3.3. The London potential

In Chapter 5 the assumption was made that the induced dipole – induced dipole interaction energy can be derived from the London potential also. In [24] the London potential for two dissimilar atoms is calculated by

\[
E_L(r) = -\frac{3}{2} \frac{\alpha_i \alpha_j}{(4\pi\epsilon_0)^2} \frac{\hbar v_i v_j}{r^6 (v_i + v_j)}
\]

(7.24)

where \( \alpha_i \) is the polarisability of the gas molecule in \( (\text{C}^2\text{m}^2)/\text{J} \) and \( \alpha_j \) the polarisability of the solid molecule. It can be replaced by \( \overline{\alpha}_{\text{solid}} \), the mean average polarisability of the solid continuum molecule calculated by equation (3.97). \( v_j \) is assumed to be the
frequency of the solid electrons in the ground state in 1/s and can be calculated by (3.98). Furthermore it is defined that

\[ I_i = h \nu_i \]  

(7.25)

where \( I_i \) is the ionisation energy of the adsorptive molecule in J. It is tabulated in literature [6]. Inserted in equation (7.24) it is

\[ E_L(r) = \frac{3}{2} \frac{\alpha_i \alpha_{\text{solid}}}{(4\pi\epsilon_0)^2 r^6} \frac{I_i \nu_0}{(I_i h + \nu_0)} \]  

(7.26)

With the general interaction energy as calculated in equation (5.40) the induced dipole – induced dipole potential is

\[ \Phi_{\text{ind}}(z) = \int_{z+\sigma_0}^{\infty} E_L(r) \rho_{j,\text{at}} 4\pi r^2 dr \]  

(7.27)

or

\[ \Phi_{\text{ind}}(x) = -\rho_{j,\text{at}} \frac{\alpha_i \alpha_{\text{solid}} I_i \nu_0}{8 \cdot \pi \epsilon_0^2 kT_{\text{ads}}} \left( \frac{I_i}{h} + \nu_0 \right) \left( \sigma_{i,j}^3 \right)^{-1} \]  

(7.28)

It can be defined an alternative interaction parameter for the induced dipole – induced dipole interaction:

\[ A_{\text{ind}} = -\rho_{j,\text{at}} \frac{\alpha_i \alpha_{\text{solid}} I_i \nu_0}{8 \cdot \pi \epsilon_0^2 kT_{\text{ads}}} \left( \frac{I_i}{h} + \nu_0 \right) \left( \sigma_{i,j}^3 \right)^{-1} \]  

(7.29)

In table 7.8 the values for \( A_{\text{ind}} \) calculated by equations (5.62) and (7.29) are compared for the case of adsorption of gases on zeolite MS5A.
Table 7.8: Interaction parameter $A_{\text{indind}}$ calculated with the two equations (5.62) and (7.29)

The values are very similar. The assumption in Chapter 5 is proved now. In this work equation (5.62) was taken to be consistent with the literature [26, 27].

7.3.4. Potential energy comparison and formula overview

The introduced model according to equations (5.61) and (6.3) is a theoretical basis for predicting isotherms of gases on microporous solids. It is derived from the potential energies which are attractive between the adsorptive and the adsorbent. In this section the main formulae of the different cases will be tabulated for engineering purposes.

As example for the acting different attraction energies the adsorption between methanol and NaY zeolite will be examined quantitatively. Between molecules of this adsorption pair all kinds of potential energy can exist. Therefore, it is ideal for the comparison of the adsorption forces. As discussed in Chapter 5 the Henry coefficient of polar gases with energetic heterogeneous microporous solids is described by the integral equation (5.61). For comparing the energies of attraction the percentage of
the energies is calculated when the adsorptive is attached on the solid surface, in other words the distance \( z \) between adsorptive and adsorbent is equal to 0. Table 7.9a gives a detailed overview of the situation. With an adsorption temperature of \( T_{\text{ads}} = 318.4 \, \text{K} \), the energy unit is \( k^*T_{\text{ads}} = 4.395 \times 10^{-21} \, \text{J} \). The other parameters are: \( \sigma_i = 4.2 \times 10^{-10} \, \text{m} \), \( \mu_i = 5.67 \times 10^{-30} \, \text{C m} \), \( \alpha_i = 3.66 \times 10^{-40} \, \text{C}^2 \, \text{m}^2/\text{J} \), \( \rho_{i,\text{at}} = 3.3 \times 10^{-28} \, \text{1/m}^3 \), \( \Phi_{\text{at}} = 8.4 \times 10^{-20} \, \text{J} \) and \( \alpha_i = 2.82 \times 10^{-40} \, \text{C}^2 \, \text{m}^2/\text{J} \).

In the case of methanol adsorption on NaY at 318.4 K there are two potentials, which contribute 97 % of the overall attraction energy, respectively the induced dipole – induced dipole and the permanent dipole – charge interactions. From the other four the two quadrupole interactions only make up 0.42 % of the overall potential. A second calculation for \( \text{CO}_2 \) on NaX at 304.55 K (table 7.9b) shows that the quadrupole - charge interaction contributes approximately 12.3 % of \( \Phi \). These two results make it clear that three potentials are eminent for the calculation of Henry coefficients: Always the induced dipole – induced dipole interaction \( \text{indind} \) and dependent from the adsorptive and the adsorbent the permanent dipole – charge interaction \( \text{dipcha} \) and/or the quadrupole moment – charge interaction \( \text{quadcha} \).

The main formulae of this work are collected in table 7.10. These are the refractive index and Hamaker constant of zeolites, the Henry coefficient for the adsorption of gases in the case of Hamaker dominant attraction energies and also for the case of polar-polar adsorption pairs and finally the new model for predicting the whole adsorption isotherm. The section in which the formula appears in a detailed description is also tabulated.
Table 7.9a: Attraction energies between methanol and NaY at a distance $z = 0$ of the adsorptive from the adsorbent surface.

8. Summary

The main objective of this thesis is the theoretical prediction of adsorption equilibria of single gaseous substances on microporous solids like active carbon or zeolites (e.g. MS4A, MS5A, NaX and NaY). A novel equilibrium model was derived from a differential equation considering two boundary conditions. These boundaries were the Henry coefficient for diluted gases and the saturation loading for highly concentrated gases.

A historical overview on adsorption is presented in Chapter 3 which also addresses some important chemical and technical aspects. An essential prerequisite for the prediction of adsorption equilibria is a detailed knowledge of the properties of the solid adsorbents. The characterisation of microporous adsorbents is treated in Section 3.3. The novel equilibrium model is compared with classical adsorption theories as the models of *Langmuir* and *Toth*. Techniques for the measurement of adsorption equilibria (e.g. adsorption isotherms) are explained also.

The *Henry* coefficient which describes the adsorption isotherm of diluted gases depends on the properties of both the gaseous (adsorptive) and the solid (adsorbent) phase. However, the key parameter of the intermolecular interaction forces, the *Hamaker* constant, is unknown for most zeolites. In Chapter 3, an approximated *Hamaker* and *de Boer* model for predicting the *Hamaker* constant of microporous solids is developed on the basis of the refractive index.

The refractive index is determined by the *Clausius-Mosotti* relationship between the relevant optical and density parameters of the solid adsorbent. For zeolitic adsorbents, the optical parameters can be derived from the polarisability of ions in the zeolite crystal.

Experimental methods for the determination of adsorption equilibria are presented in Chapter 4 of this thesis. Besides classical techniques some novel ones are treated in detail, e.g. the zero length column method.
An important result of the thesis is the finding that the adsorption of unpolar as well as polar gases on energetical heterogeneous adsorbents is controlled by the Hamaker constant. Therefore, the dominant mechanism is the induced dipole – induced dipole interaction. For this case the dimensionless Henry curve was numerically evaluated because the differential equation cannot be solved analytically. The numerical results were correlated by an exponential function. The adsorption of polar gases on energetical heterogeneous adsorbents depends on more than two parameters. It was not possible to correlate the numerical results by simple regression. Nevertheless, a suited algorithm is presented in Chapter 5.

In Chapter 6, the prediction model for all cases was developed by integrating the fundamental differential equation under consideration of two boundary conditions, e.g. the Henry coefficient and the saturation loading.

In Chapter 7 the novel model was compared with literature and experimental data. The Toth isotherm model was used to calculate the experimental Henry coefficients. The calculated Henry coefficients of the novel model fit very well with experimental data over six orders of magnitudes. As second step the predicted adsorption equilibria were compared with experimental data from the literature. The novel model fits the isotherms very well beginning at the Henry region and ending at the saturation region. Next in Chapter 7, the assumptions for the calculation of the adsorption model parameters, e.g. the refractive index, were verified. For engineering purposes it is important to know which attraction potentials are of theoretical interest only and which are dominant for calculating the Henry coefficient. As a result it was shown that the induced dipole – induced dipole interaction is always eminent. For polar gases additionally the permanent dipole – charge and/or the quadrupole moment – charge interaction have to be taken into account. All other induced dipole interactions have minimal impact and can be neglected.

In the appendix the set-up for own experimental data will be explained.
Appendix

Appendix A: Isotherms in transcendental form

Maurer [26] introduced a generalized empirical equation that allows for a priori predictions of complete adsorption isotherms for active carbon with

\[ He \ p = n \exp \left( f(S_{BET}) \frac{T_c/K}{(p_c/bar)^2} \frac{n}{mol/kg} \right) \]  \hspace{1cm} (A.1)

where \( He \) is the Henry coefficient in mol/(kg*Pa), \( p \) the adsorption equilibrium pressure in Pa, \( n \) the loading of the adsorbent in mol/kg, \( T_c \) the critical temperature of the adsorptive in K and \( p_c \) the critical pressure of the adsorptive in bar. \( f(S_{BET}) \) is a function of the BET surface area \( S_{BET} \) and follows from

\[ f(S_{BET}) = -0.367 + \frac{6167}{S_{BET} m^2} \] \hspace{1cm} (A.2)

The Henry coefficient can be determined by the following equation for energetic homogeneous adsorbents, derived in Chapter 5 with

\[ He = \frac{\sigma_{ij} S_{BET}}{\mathcal{R} T_{ads}} IL = \frac{\sigma_{ij} S_{BET}}{\mathcal{R} T_{ads}} \exp \left( p_1 I P_{p_2} \right) = \frac{\sigma_{ij} S_{BET}}{\mathcal{R} T_{ads}} \exp \left( p_1 \left( \frac{T_c}{T_{ads}} \sqrt{\frac{2 H a_j}{\pi \sigma_j^3 p_c}} \right)^{p_2} \right) \] \hspace{1cm} (A.3)

where all the coefficients are in SI units and explained already in Chapter 5. The parameters are \( p_1 = 0.3313 \) and \( p_2 = 1.180 \). The loading \( n \) can be calculated by given partial pressure \( p \).
Equation (A.2) cannot be solved analytically for n. The given function has the structure

\[ y(x) = x \exp(ux) \]  

(A.4)

The inverse function of equation (A.4) is the so-called *Lambert* function \( W \) with

\[ x = \frac{W(uy)}{u} \]  

(A.5)

where \( y \) is a substitution for

\[ y = He \ p \]  

(A.6)

and the parameter \( u \) a substitution for

\[ u = f(S_{BET}) \frac{T_c/K}{(p_c/\text{bar})^2} \]  

(A.7)

*Rechid* [104] introduced a mathematical approach for describing the *Lambert* function with analytically solvable functions. It is therefore

\[ n = \frac{1.0004 \ln(uy + 1) - 2.1037 \ln(\ln(uy + 1) + 1) + 2.3948 \ln(\ln(\ln(uy + 1) + 1) + 1)}{u} \]  

(A.8)

The adsorption isotherm for active carbon can be calculated straight forward analytically only with knowledge of the properties of adsorptive and adsorbent. As example the isotherm of ethane on active carbon is shown in figure A.1. The parameters are listed in table A.1.
Table A.1: Parameters for the adsorption isotherm of ethane on active carbon.

</tbody>
</table>

The experimental values of the adsorption isotherm are compared with the adjusted Toth isotherm and the predictive isotherm calculated with equation (A.8). The Toth isotherm parameter $1/K_T$ is given in the literature example in kPa [105], so the partial pressure $p$ in the Toth isotherm has to be inserted also in kPa.
**Figure A.1:** Adsorption isotherm of ethane on active carbon at $T_{\text{ads}} = 303.15$ K.

**Figure A.2:** Adsorption isotherm of ethane on active carbon at $T_{\text{ads}} = 303.15$ K in a double logarithmic plot.
With given loading $n$ the partial pressure $p$ of the adsorption isotherm can be calculated by

$$p = \frac{n \exp\left(f(S_{\text{BET}}) \frac{T_c/K}{(p_c/\text{bar})^2 \text{mol/kg}} \frac{n}{He} \right)}{n \exp\left(f(S_{\text{BET}}) \frac{T_c/K}{(p_c/\text{bar})^2 \text{mol/kg}} \frac{n}{He} \right)}$$

(A.9)

With equations (A.8) and (A.9) the adsorption isotherm of any adsorptive on activated carbon can be calculated analytically in both directions.

**Appendix B: Materials and Methods**

This study is based on both literature data and own adsorption experiments. Experimental *Henry* coefficients were calculated by *Langmuir* and *Toth* isotherm adaptions. *Henry* coefficients in the literature were taken from tables or calculated by regressing the isotherm data with *Langmuir* and *Toth* parameters.

**B.1. Materials**

**B.1.1. Experimental data**

Adsorption experiments were conducted at the Lehrstuhl für Technische Chemie II of the Technische Universität München in Garching and at the Institut für Nichtklassische Chemie e.V. at the Universität Leipzig. In tables B.1 and B.2 the used adsorptives and adsorbents and their relevant properties are listed.
Table B.1: Adsorptives used for adsorption isotherms with their properties.

The methanol had a purity of 99.9 mass-%. For experiments in Garching it was a Merck product with the trade name Uvasol and is normally used for spectroscopy purposes. Methanol adsorption experiments in Leipzig were conducted with the Merck product LiChrosolv which is suitable for liquid chromatography purposes. The dichloromethane had a purity of 99.8 mass-%. For experiments in Garching it was a Sigma-Aldrich product with the trade name AMD Chromosolv and is normally used for chromatography purposes. Dichloromethane adsorption experiments in Leipzig were conducted with the Merck product pro analysi. The adsorbents MS5A and NaX were from Grace Davison. MS5A has the trade name Sylobead MS C 522 and NaX (13X) the trade name Sylobead MS C 544. The adsorbent NaY were from Akzo Nobel.

Methanol is a high value chemical in many processes, e.g. the conversion to highly knockproofed gasoline via zeolite catalysts. Dichloromethane is a solvent for resins, fats and plastics. Both adsorptives have a medium dipole moment, high enough to dominate with their dipole/charge potential the Hamaker potential and small enough to get into the Henry region with a gravimetric experimental set-up when adsorbed on zeolites. The zeolites MS5A, NaX and NaY are standard adsorbents in many chemical processes like removal of pollutants.

B.1.2. Literature data

Literature data were collected and analyses was made for verifying the models derived in this study [1, 3, 5, 7, 8, 9, 11, 12, 13, 18, 20, 22, 23, 25, 28, 29, 31, 33, 34, 35, 36, 37, 38, 39, 40, 45, 60, 91, 92, 115, 116, 117]. Henry coefficients were tabulated in most of the cases, if not the adsorption isotherms were analysed by using the Langmuir plot explained in Chapter 3 or with Langmuir parameter regressing in the program Origin or with Toth isotherm regressing. The properties of the adsorptives were found in Reid et al. [106] and in the CRC Handbook [6]. Especially quadrupole moments were found in the Computational Chemistry Comparison and Benchmark Database [107] and in further literature [2, 14, 15, 16, 17, 42, 43, 103]. The examined adsorptives and adsorbents with their properties are listed in appendix C and appendix D, respectively.
B.2. Experimental set-up

B.2.1. Adsorption isotherm measurements

The adsorption equilibrium isotherms were measured at the Lehrstuhl für Technische Chemie 2 of the Technische Universität München gravimetrically in a modified SETARAM TG-DSC 111 microbalance (see figure B.1) which is able to measure differences in mass down to $10^{-6}$ g which is also the accuracy. The sample weight in the microbalance was applied between 13 to 22 mg in order to record precise measurement and better signal-to-noise ratio. The pressure inside the system can be reduced down to $10^{-7}$ mbar with a Pfeiffer turbo molecular pump and the temperatures can be applied within the range of 25°C to 750°C with an accuracy of 0.15°C. The high vacuum was measured with a Pfeiffer TPG 300 pressure transducer. The experiments were carried out in the pressure range from $10^{-3}$ to 13 mbar (0.1 Pa to 1300 Pa), measured with a BARATRON 122 A pressure transducer. The transducer has an accuracy of 0.5 % of reading [108]. For activation, the solid samples were heated in vacuum ($p < 10^{-6}$ mbar) to 500 °C with 10 °C/min and held 4 h at 500 °C. After activation, the temperature was reduced to ca. 45°C. The liquid sorbates were added in pulses to the high vacuum system in which they vaporised. After each pulse the system was equilibrated. This was monitored by observation of the sample weight and pressure. The system was regarded to be in steady state or equilibrium, when changes in any of the parameters pressure, mass or heating flux were not observed any more [110]. Figure B.2 shows the experimental set-up.

Figure B.1: SETARAM TG-DSC 111 microbalance.
The data for the adsorption isotherm graphs were calculated by the following method: The adsorbents are hold by a crucible in the microbalance. Its mass after activating is the so-called blank mass $m_0$. The mass of the crucible with activated adsorbent is the mass $m_1$. After equilibrium of the injected adsorptive with the adsorbent the new absolute mass $m_{i+1}$ is measured. So one can calculate the equilibrium loading $n_{i+1}$ of every adsorption step with its equilibrium pressure could be measured by

$$n_{i+1} = \frac{m_{i+1} - m_1}{m_0} \frac{1}{M_{\text{adsorptive}}} \quad \text{for } i > 1$$

where the masses are in kg and $M_{\text{adsorptive}}$ is the molar mass of the adsorptive in kg/mol. With equation (B.1) the equilibrium loading $n$ in mol/kg regarding to the equilibrium pressure $p$ in Pa is obtained.
The adsorption equilibrium isotherms at the Institut für Nichtklassische Chemie e.V. from the Universität Leipzig were measured gravimetrically with a high resolution magnetic suspension balance from Rubotherm Präzisionsmesstechnik GmbH which had a weighing instrument from Mettler-Toledo of type AT261. The sample weight in the microbalance was applied between 10 to 30 g. The relative error of this instrument is 0.002 % of the measured value and its resolution is 0.01 mg [113]. The pressure inside the system can be reduced down to 10^{-3} mbar with a Pfeiffer turbo molecular pump TMH 071P and the temperatures can be applied within the range of 25°C to 400°C with an accuracy of 0.15°C of the used PT100 sensor. The high vacuum was measured with an MKS pressure transducer, Baratron Model 627B, and the low vacuum with a Newport/Omega pressure transducer, Model SN2713. The experiments were carried out in the pressure range from 10^{-1} mbar to 1 bar (10 Pa to 100,000 Pa). The transducers had an accuracy of 0.12 % of reading for the MKS model and 0.03 % of the end value 1 bar for the Newport/Omega model [114]. For activation, the solid samples were heated in vacuum (p < 10^{-3} mbar) to 370°C with 1 K/min and held 10 h at 370°C. After activation, the temperature was reduced to 323 K. The liquid sorbates were degassed after condensing with liquid nitrogen with a vacuum pump from ATS Antriebstechnik GmbH. This was done several times. After this the sample was added in pulses to the high vacuum system in which they vaporised. After each pulse the system was equilibrated. This was monitored by observation of the sample weight and pressure. The system was regarded to be in steady state or equilibrium, when changes in any of the parameters were not observed. Figure B.3 shows the experimental set-up.

Figure B.3: Experimental set-up for adsorption isotherm measurements in Leipzig.
The data for the adsorption isotherm graphs were calculated by the same method as described above for equation (B.1).

In general the first set-up was taken for high-vacuum measurements from 0.1 Pa to 100 Pa and the second set-up for medium-vacuum measurements from 100 Pa to saturation pressure of the adsorptive at room temperature.

### B.2.2. BET surface and micropore volume measurements

BET surface measurements were conducted with nitrogen at 77 K as described in Chapter 3. The micropore volume of the adsorbents were derived from t-plot analysis. Results are listed in table B.2.
B.2.3. Adsorptive data

Appendix C: Alternative way for deriving the potential factor \( f_{\text{quadcha}} \)

In Section 5.1 the assumption has been made that no permanent dipole or quadrupole in an adsorbent molecule is existing and in Section 5.2.1 it has been stated that the time averaged dipole moment is zero. However, a strong quadrupole moment \( Q_i \) with a certain structure can induce a dipole moment \( \mu_i \) in an adsorbent molecule. The ratio between the moments \( \mu_i \) and \( Q_i \) of an adsorptive molecule can be derived when equation (5.57) is divided by equation (5.51):

\[
\frac{Q_i^2}{\mu_i^2 (\sigma_{i,j} + z)^2} = 20
\]

(C.1)

or for \( z = 0 \) (maximum value of \( Q_i \) for a given \( \mu_i \))

\[
Q_i = \sqrt{20} \mu_i \sigma_{i,j}
\]

(C.2)

The only adsorptive molecule with a strong quadrupole moment but a rather dipole moment already often investigated with respect to adsorption isotherms is CO\(_2\) \((Q_i = 15\times10^{-40} \text{ Cm}^2, \mu_i = 2.34\times10^{-30} \text{ Cm})\). In the previous sections the potential factors \( f_{\text{dipcha}} = f_{\text{indcha}} = 1.35 \). An agreement between experimental results for the system CO\(_2\)-MS4A is given if the dimensionless energy \(-\frac{\Phi_{\text{quadcha}}}{kT_{\text{ads}}}\) in equation (5.57) is multiplied by the factor 8 which leads to \( f_{\text{quadcha}} = 1.35/8 \). As a first approach it is further assumed that the induced dipole moment \( \mu_j \) (permanent due to the close neighborhood of a quadrupole moment \( Q_i \)) is related. Now an effective quadrupole moment \( Q_{i,\text{eff}} \) is introduced which takes into account the interaction between \( Q_i \) and \( \mu_i \). With \( \sigma_{i,j} = 4.05\times10^{-10} \text{ m} \) and \( \mu_i = \mu_j \) we find
\[ Q_{i,\text{eff}} = \sqrt{20\mu_i\sigma_{i,i}} = 42.4 \times 10^{-40} \text{ Cm}^2 \]  \hspace{1cm} (C.3)

and finally

\[
\left( \frac{Q_{i,\text{eff}}}{Q_i} \right)^2 = \left( \frac{42.4 \times 10^{-40}}{15.0 \times 10^{-40}} \right)^2 = 8
\]  \hspace{1cm} (C.4)

It is stressed here that the hypothesis here presented should be tested by experimental results, for instance by experimental data of the system C_2H_2F_4/zeolite.
